Preface

Welcome to the second edition of *Encyclopedia of Dietary Supplements*, reflecting the combined efforts of more than 100 authors from 13 countries on 97 topics. Response to the first edition, published in 2005 and then supplemented by a series of online chapters, prompted us to revise and expand the Encyclopedia. There has been considerable expansion in research on many dietary supplements and their ingredients. We expect that this Encyclopedia will continue to be a valuable reference for students and researchers in physiology and chemistry, for health care providers, and for consumers who are interested in understanding the kind of science that is—or is not—behind the claims that are made for dietary supplements that are sold throughout the world, where standards of government regulation differ from country to country. In the United States, sales of products in the dietary supplement market approached \$25 billion in 2009. Their form and their labeling are regulated by the Food and Drug Administration (FDA) as a result of legislation passed in 1994 called the Dietary Supplement Health and Education Act (DSHEA). The dietary supplement category in the United States includes vitamins, minerals, and other ingredients that are found in foods, as well as ingredients not ordinarily found in foods—such as extracts of herbs and other natural products—that are used by consumers for their potential health-promoting, disease-preventing, or performance-enhancing properties. Many of these are represented in the chapters of this book.

The Encyclopedia is not just for consumers in the U.S. market, although we acknowledge that the term “dietary supplements” is an American expression. We are not aware of any other single term that describes all of the substances that we wish to include in this Encyclopedia, although terms such as food supplements, nutritional supplements, or natural health products have been applied as well. Sometimes the claims for benefit of specific products are borne out by well-documented scientific studies. In other cases, they are not, or the science to support their use is still at an early stage. Enthusiasm for their use may be based on popular legend or on longstanding patterns of use in traditional healing systems. In this book, we hope that readers will be able to examine the types of evidence that have been used to support claims of benefit and safety.

The goal of this book is to provide readers with comprehensive, yet accessible, information on the current state of science for individual supplement ingredients or extracts. To this end, each entry reviews basic information available about the ingredient including, where applicable, its chemistry and functions, before detailing the preclinical and clinical literature. Articles conclude with references to the relevant literature.

Given the large number of dietary supplement products in commerce, this book covers only a small fraction of them, with selection based primarily on the frequency of their use and the availability of a sufficient science base to discuss their efficacy and safety. It is clear that the level of scientific information available differs markedly among the various entries. For many ingredients, the chemistry and physiology, preclinical and clinical information, and mechanism of action are well known. For others, by contrast, some or many pieces of these data are missing. The preparation of some commercial products is of high quality and follows good agricultural, laboratory, and manufacturing practices. Again, by contrast, the preparations for others have not been reliable, making them subject to high variability in content and possible contamination. As dietary supplement use becomes more widespread, there are growing concerns about safety of some ingredients, including possible harmful interactions between supplements and prescribed drugs. When known, this information is included in the chapters of this book. These issues should form the basis for future research.

The field of dietary supplements is a rich one, and the science related to this large class of ingredients is expanding all the time. All the chapters that appeared in the first edition have been revised and updated for this edition. In addition to providing these updated chapters, we have included 12 additional chapters on topics not previously covered, reflecting the emergence of dietary supplements in the marketplace, as well as the science behind them. There is also a new chapter on the challenges of dietary supplement research. Additional changes involve gathering several related chapters under “umbrella” topics: *Carotenoids* and *Polyphenols*. Two of the chapters in this edition of the Encyclopedia, on *Ephedra* and *Androstenedione*, were commissioned before their status as dietary supplements in the U.S. market was changed. In 2004, the FDA banned ephedra-containing products from the dietary supplement market in the United States. Also in 2004, the FDA issued warning letters to companies then marketing products containing androstenedione; the regulatory status of these products as dietary supplements has therefore changed. Nevertheless, until recently, both ephedra and androstenedione were widely consumed in the United States. We felt, therefore, that discussion of the science of these ingredients was important. The chapters have been updated to reflect the new regulatory status of these ingredients.

Where possible and applicable, chapter names for botanical ingredients have been adapted to conform to the standardized common names in the American Herbal

Products Association's *Herbs of Commerce*, Second Edition (2000). The accepted scientific names (with authority) and additional synonyms may be found in the individual chapters.

We express our thanks to the authors of the individual chapters. This is a challenging and somewhat controversial field, but we believe that our authors have provided a balanced and current view of the literature. We also acknowledge with gratitude the hard work and guidance of Informa Healthcare's editorial staff, particularly the project editor, Timothy DeWerff.

Finally, we wish to emphasize that the inclusion of chapters on particular dietary supplements in this Encyclopedia does not imply that we endorse them.

The Challenges of Dietary Supplement Research and Considerations for Future Studies

D. Craig Hopp and Catherine M. Meyers

INTRODUCTION

The American public and the popular press have considerable interest in the use of dietary supplements (1,2). In view of observed widespread use, there is a need for further information regarding dietary supplement products and their potential clinical applications. This report presents recently compiled data on dietary supplement use in the United States and discusses primary considerations for further research in this area. These considerations focus largely on the need for a standard approach to product characterization and the need to develop an appropriate knowledge base for individual products, prior to embarking on large multicenter trials assessing product efficacy.

BACKGROUND ON DIETARY SUPPLEMENT USE IN THE UNITED STATES

Findings from the 2007 National Health Interview Survey (NHIS), conducted by the Centers for Disease Control and Prevention's National Center for Health Statistics, have provided extensive information on dietary supplement use by the American public (1). The NHIS is an annual in-person survey of Americans regarding their health- and illness-related experiences. The 2007 NHIS included a complementary and alternative medicine (CAM) section and collected information from nearly 24,000 adults, as well as nearly 9500 children under the age of 18 years.

The 2007 NHIS data (Table 1) reveal that approximately 38% of adults, nearly 39 million Americans, use some form of CAM therapy and further that nearly 18% of adults use at least one nonvitamin, nonmineral dietary supplement (1). Similarly, approximately 12% of children less than 18 years of age use some form of CAM therapy, with nearly 4% using at least one dietary supplement (1). The most common reason provided for dietary supplement use is for enhancing wellness (40%). Another 35% of respondents indicate that dietary supplements are used for both wellness and for treatment of a specific condition, whereas only 20% relate that dietary supplements are used to treat a specific condition. The most common health conditions related to CAM product use are those associated with chronic pain, largely of musculoskeletal origin (1).

The most commonly used dietary supplements reported in the 2007 NHIS are listed in Table 2 (1). The 10

Table 1 The 10 Most Common CAM Therapies Used in U.S. Adults—2007^a

Therapy	Prevalence (%)
Dietary supplements	17.7
Deep breathing	12.7
Meditation	9.4
Chiropractic and osteopathic	8.6
Massage	8.3
Yoga	6.1
Diet-based therapies	3.6
Progressive relaxation	2.9
Guided imagery	2.2
Homeopathic treatment	1.8

	Prevalence (%)
Adults	
Fish oil/ ω -3	37.4
Glucosamine	19.9
Echinacea	19.8
Flaxseed oil/pills	15.9
Ginseng	14.1
Combination herb pills	13.0
Ginkgo biloba	11.3
Chondroitin	11.2
Garlic supplements	11.0
Coenzyme Q10	8.7
Children	
Echinacea	37.2
Fish oil/ ω -3	30.5
Combination herb pills	17.9
Flaxseed oil/pills	16.7

^aSource: Adapted from Ref. 1.

most commonly used products in adult respondents are fish oil or ω -3 fatty acids, including docosahexaenoic acid, glucosamine, echinacea, flaxseed oil or pills, ginseng combination herb pills, ginkgo biloba, chondroitin, garlic supplements, and coenzyme Q10. Most dietary supplement use reported for children in the United States is focused on four products: echinacea (37.2%), fish oil or ω -3 fatty acids (30.5%), combination herb pills (17.9%), and flaxseed oil or pills (16.7%) (1).

Use of CAM therapies, including dietary supplements, is widespread across all demographic groups of the U.S. population (1,2) and is more prevalent in women

than in men, with regional variability, in that the use is more prevalent in the West than in the Midwest, Northeast, or Southern regions of the United States. Greater use of CAM therapies is observed between the ages of 30 and 69 years and is also associated with higher levels of education, former smokers, and reported regular levels of physical activity. CAM therapy use is also higher in respondents who report more health conditions or doctor visits, although 20% of CAM users did not report underlying health conditions (1,2).

In view of this extensive use, there is a need for further study of dietary supplements. Rigorous testing of individual dietary supplements, however, is frequently limited because of lack of critical information on several product attributes. In particular, lack of information on product characterization, purity, active ingredients, pharmacokinetics, potential mechanisms of action, or biomarkers for activity limits early phase testing of products. Lack of dosing information and definition of appropriate clinical outcome measures also limit planning of clinical trials. A more standardized approach to product characterization and development of a richer knowledge base on individual supplements will be essential to advancing investigative efforts in this field.

PRODUCT INTEGRITY ISSUES FOR DIETARY SUPPLEMENT RESEARCH

One of the unique challenges inherent to dietary supplement research is that the product complexity is highly variable. This issue poses a serious challenge to establishing a "standard" list of quality control procedures for these products. Although single-component supplements such as resveratrol or melatonin can be accurately characterized and exactly reproduced, plant extracts are much more complex. Furthermore, as has been widely documented, there can be considerable inconsistency in batch-to-batch, bottle-to-bottle, and brand-to-brand content of "off-the-shelf" dietary supplements (3). For botanical products, there is a high level of complexity and natural variability, which prevent investigators from entirely characterizing or exactly reproducing a particular extract. It is estimated that individual plant species are capable of producing thousands of metabolites at varying concentrations. Additional variables for these products include the observation that the same species grown in different places, or even different years in the same place, will not generate the same metabolic profile. It is therefore apparent that a certain amount of product variability, for some supplements, is to be expected. Despite these obstacles, researchers must still strive to conduct a thorough analysis of products used for research purposes. Extensive characterization of research materials is a necessary initial step so that subsequent study results can be appropriately interpreted and reliably reproduced.

It is also apparent that comprehensive characterization, especially for botanical products, can require an enormous amount of effort and expense. Products typically pass through several hands from the grower to the processor and the distributor, prior to arrival at the vendor, and possibly others before reaching consumers. It can be very difficult and sometimes impossible to trace a

given product back to its origins. Furthermore, the identity of every minor component in an extract is almost never known. However, with some important exceptions, this degree of detail in product characterization is neither necessary nor practical. A pragmatic approach is to establish quality control methods that are appropriate for the complexity of the product, the proposed research plan, and product's intended use.

A clinical trial testing a herbal extract will require a substantial dossier of information to document safety, stability, and reproducibility of that product. This dossier will include detailed knowledge about every step in the chain of custody of that material from the time it was grown to the time it was administered to patients. The U.S. Food and Drug Administration (FDA) released a guidance document for botanical drugs in 2004, which is an appropriate resource on quality control procedures to follow for randomized controlled trials (RCTs) of herbal products (4). Investigators intending to conduct clinical studies are strongly encouraged to contact FDA and determine whether an IND (investigational new drug) application is needed for the study of a product in the United States. If an IND is needed for a given study, FDA will provide specific guidance regarding type of information required and level of detail for product characterization.

The characterization requirements for complex products used for *in vitro* studies are perhaps less clear. Similarly, the requirements for early-stage clinical studies on refined products that are botanically derived, but far less complex than the parent extract from which they originated, are less well defined. In these examples, it might be argued that the focus should be more on accurate product characterization. High-pressure liquid chromatography is the analytical technique most commonly employed for generating a product "fingerprint," but there are other methods that could be appropriate depending on the sample. This fingerprint, regardless of the method used to generate it, establishes the identity of a given product without having to know the identity of every product component. Furthermore, it sets a reference point that can be used to document batch-to-batch reproducibility and assess product stability over time. Whichever analytical technique is chosen, the fingerprint must be unique enough to distinguish it from related products and sensitive enough to detect significant changes over time. As the particular dietary supplement research progresses into animals and ultimately humans, progressively more information will be needed regarding product origin and its manufacturing process. A realistic balance should be sought between the need for further studies of dietary supplements and the need for extensive product characterization prior to beginning research studies. Such a balance will ensure the feasibility of future research efforts on these products.

Investigators need to be cognizant of the need for product characterization even in early stages of dietary supplement research. Part of this effort involves independent product analysis, either by the investigator or third party laboratory, to confirm specifications provided by the supplier. This early-stage testing must be conducted regardless of product complexity. Even "pure" compounds from widely known manufacturers have been noted to be mislabeled, in that the content analysis demonstrated that the marketed product was not consistent

with label specifications. For products that have not been extensively studied, it may not be feasible to have an independent analysis performed as validated methods may not be available. Moreover, developing or implementing new methods for such products can represent an appropriate independent research endeavor. In such cases, the information provided requires close scrutiny to determine whether additional product concerns remain.

Finally, another important product consideration for investigating dietary supplements focuses on familiarity with the product supplier. Whenever possible, investigators should begin cultivating relationships with the product supplier at early stages of their research and start acquiring information that will be required for future studies. It is important to determine early in the course of investigations whether the supplier has stringent quality control procedures in place and whether they will provide the requisite product documentation. This is especially true if the ultimate goal is to develop a knowledge base necessary for performing clinical studies. It is therefore prudent to select suppliers or vendors that have provided products for other research studies and have a track record of supplying test materials with the requisite documentation.

CONSIDERATIONS FOR CLINICAL STUDIES OF DIETARY SUPPLEMENTS

Clinical studies are an essential tool for assessing safety and efficacy of therapeutic interventions, whether they are conventional drugs, medical devices, or dietary supplements (5). Similar to standards for assessing efficacy of pharmaceuticals, RCTs play a major role in determining whether a compound or product is safe and effective for a specific indication (5). Prior to initiating (phase III) RCTs, however, there is substantial information that should be collected on a given product. In the pharmaceutical industry, extensive preliminary preclinical and clinical studies (i.e., pharmacokinetics, dosing strategies) are typically undertaken prior to performing large multicenter trials, due to regulatory requirements enforced by FDA. There is a similar need for extensive preliminary studies for dietary supplement investigations, particularly when the research question for the study includes treatment of a disease or condition.

It is important to develop a knowledge base for individual dietary supplements, which will provide direction for further clinical investigations. The optimum knowledge base for a product includes information on mechanism(s) of action, clinical chemistry, biomarkers for in vivo effect, appropriate clinical outcome measures, and the target patient population for the product. For many dietary supplements, information is lacking on many aspects of this knowledge base, which has hampered progress in conducting definitive clinical studies.

As discussed in the previous section, it is essential to have standardized data collection on product characterization, as well as pharmacokinetics, prior to embarking on clinical trials of dietary supplements. In addition, collecting adequate data regarding dosing, potential toxicity, and development of an appropriate placebo for a given product are also requisite early tasks prior to designing

clinical trials. For some dietary supplements, product taste or odor may significantly limit the ability to generate an acceptable placebo for clinical testing.

Understanding the putative mechanism of action of a given product is also an important aspect of the knowledge base, as it strengthens the plausibility of the intervention, and, most importantly facilitates identification of biomarkers to document in vivo effect of the dietary supplement. Availability of a biomarker that can be used to document activity of the agents is of great value. A biomarker facilitates a rational approach to dosing, makes it possible to determine which patients are responding to the intervention, and can assist in identification of outcome measures that are maximally sensitive. The absence of this information can limit expansion of clinical studies beyond early phase testing, particularly for products such as dietary supplements that are generally anticipated to have mild to modest clinical effects.

In planning informative large RCTs, it is essential to have standardized outcome measures that are maximally sensitive and can reliably be implemented in the context of a clinical trial (5). It is also important to have adequate preliminary data on the target patient population before embarking on a large clinical trial (5). Although the primary standard for establishing safety and efficacy remains the RCT, early-phase investigations can exploit other design strategies. For example, adaptive trial designs or n-of-1 designs could be used for expanding the knowledge base on individual products prior to planning subsequent larger studies.

Recent trends in clinical trial design have attempted to facilitate methods for improving trial strategies for medical product development. In clinical studies of new potential therapies, investigators and regulatory agencies have considered adaptations in early-phase trials before planning a large-scale confirmatory phase III RCT (6). To facilitate optimizing final trial design, adaptations in interventional studies may include changes in sample size, enrollment criteria (target subject population), product dose, study end points, and statistical methods for analysis of clinical outcome data (6). As previously discussed, the knowledge base for many products is lacking in several critical aspects, including target subject population, dose, and appropriate end points. Although adaptive design methods provide a mechanism for informed changes to study design after study initiation, appropriate analytic methods must be implemented in the planning of studies such that the scientific validity and integrity of the study are maintained (6).

As dietary supplements are frequently used for chronic conditions, individualized medication effectiveness tests (n-of-1 trials) have been considered a potential strategy for specific products (7,8). Unlike the RCT design, n-of-1 trials are individualized within-patient, are randomized and placebo-controlled, and include multiple crossover comparisons of product versus placebo, or versus another active treatment (7,8). Also unlike the RCT, the n-of-1 trial provides a mechanism for assessing intervention effects in individual patients who might not otherwise be included in the targeted RCT subject population (7,8). The use of such less commonly employed designs can provide a means for adequate data collection, markedly enhancing a product's knowledge base, such

that more definitive clinical trials can be optimally designed and implemented.

CONCLUSION

In developing productive research programs for dietary supplements, it is important to build a hierarchy of evidence for individual supplements, including understanding essentials of individual product characterization, basic product clinical chemistry, and subsequent rigorous testing in the setting of clinical studies. Multiple lines of investigation can then be coordinated for enhancing the knowledge base on a product, with the goal of informing practitioners and the public on safety and efficacy of dietary supplement use.

S-Adenosylmethionine

José M. Mato and Shelly C. Lu

ABBREVIATIONS

CSF, cerebrospinal fluid; GNMT, glycine *N*-methyltransferase; GSH, glutathione; HCC, hepatocellular carcinoma; Hcy, homocysteine; MAT, methionine adenosyltransferase; MTA, 5'-deoxy-5'-methylthioadenosine; MTHFR, 5,10-methylenetetrahydrofolate reductase; NASH, nonalcoholic steatohepatitis; SAH, (S)-adenosylhomocysteine; SAME, (S)-adenosylmethionine.

INTRODUCTION

Common and Scientific Name

S-Adenosyl-L-methionine, also known as 5'-[(3-Amino-3-carboxypropyl) methylsulfonio]-5'-deoxyadenosine; (S)-(5'-desoxyadenosin-5-yl) methionine; $[C_{15}H_{23}N_6O_5S]^+$, is abbreviated in the scientific literature as AdoMet, SAM, or SAME. In the early literature, before the identification of its structure, SAME was known as "active methionine."

General Description

SAME was discovered in 1953 and since then has been shown to regulate key cellular functions such as differentiation, growth, and apoptosis. Abnormal SAME content has been linked to the development of experimental and human liver disease, and this led to the examination of the effect of SAME supplementation in various animal models of liver disease and in patients with liver disease. Both serum and cerebrospinal fluid (CSF) levels of SAME have been reported to be low in depressed patients, which has led to the examination of the effect of SAME treatment in this condition. The effect of SAME in the treatment of other diseases, such as osteoarthritis, has also been investigated. This chapter reviews (i) the biochemistry and functions of SAME; (ii) altered SAME metabolism in liver disease; (iii) SAME deficiency in depression; and (iv) the effect of SAME treatment in liver disease, depression, and osteoarthritis.

BIOCHEMISTRY AND FUNCTIONS

SAME Discovery

Although SAME was discovered by Giulio Cantoni in 1953, the story of this molecule begins in 1890 with Wilhelm His when he fed pyridine to dogs and isolated *N*-methylpyridine from the urine and emphasized the need to demonstrate both the origin of the methyl group as well as the mechanism for its addition to the pyridine (1). Both questions were addressed by Vincent du Vigneaud who, during the late 1930s, demonstrated that the sulfur atom of methionine was

converted to cysteine through the "transsulfuration" pathway and discovered the "transmethylation" pathway, that is, the exchange of methyl groups between methionine, choline, betaine, and creatine. In 1951, Cantoni demonstrated that a liver homogenate supplemented with ATP and methionine converted nicotinamide to *N*-methylnicotinamide. Two years later, he established that methionine and ATP reacted to form a product, that he originally called "Active Methionine," capable of transferring its methyl group to nicotinamide, or guanidoacetic acid, to form *N*-methylmethionine, or creatine in the absence of ATP, which, after determination of its structure, he called "AdoMet" (Fig. 1). Subsequently, Cantoni and his colleagues discovered the enzyme that synthesizes SAME, methionine adenosyltransferase (MAT); (S)-adenosylhomocysteine (SAH), the product of transmethylation reactions; and SAH hydrolase, the enzyme that converts SAH into adenosine and homocysteine (Hcy). At about the same time, Bennett discovered that folate and vitamin B₁₂ could replace choline as a source of methyl groups in rats maintained on diets containing Hcy in place of methionine, a finding that led to the discovery of methionine synthase (MS). In 1961, Tabor demonstrated that the propylamino moiety of SAME is converted via a series of enzymatic steps to spermidine and spermine. In the biosynthesis of polyamines, 5'-deoxy-5'-methylthioadenosine (MTA) was identified as an end product. Thus, by the beginning of the 1960s, Laster's group could finally provide an integrated view, similar to that depicted in Figure 2, combining the transmethylation and transsulfuration pathways with polyamine synthesis.

Since then, SAME has been shown to donate (i) its methyl group to a large variety of acceptor molecules including DNA, RNA, phospholipids, and proteins; (ii) its sulfur atom, via a series of reactions, to cysteine and glutathione (GSH), a major cellular antioxidant; (iii) its propylamino group to polyamines, which are required for cell growth; and (iv) its MTA moiety, via a complex set of enzymatic reactions known as the "methionine salvage pathway," to the resynthesis of this amino acid. All these reactions can affect a wide spectrum of biological processes ranging from metal detoxication and catecholamine metabolism to membrane fluidity, gene expression, cell growth, differentiation, and apoptosis (2), to establish what Cantoni called the "AdoMet Empire."

SAME Synthesis and Metabolism

MAT is an enzyme extremely well conserved through evolution with 59% sequence homology between the human and *Escherichia coli* isoenzymes. In mammals, there are

Figure 1 Structure of SAm. (S)-adenosylmethionine (SAm) has been shown to donate: (i) its methyl group to a large variety of acceptor molecules including DNA, RNA, phospholipids, and proteins; (ii) its sulfur atom, via a series of reactions, to cysteine and glutathione, a major cellular antioxidant; (iii) its propylamino group to polyamines, which are required for cell growth; and (iv) its MTA moiety, via a complex set of enzymatic reactions known as the “methionine salvation pathway,” to the resynthesis of this amino acid.

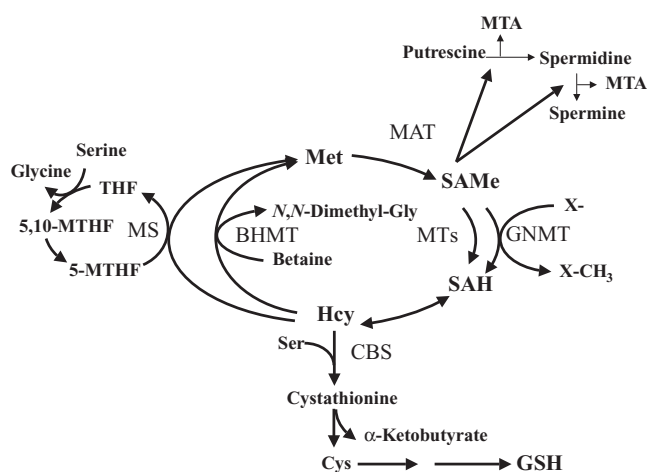

Figure 2 Hepatic metabolism of SAm. Methionine (Met) is converted into homocysteine (Hcy) via (S)-adenosylmethionine (SAm) and (S)-adenosylhomocysteine (SAH). The conversion of Met into SAm is catalyzed by methionine adenosyltransferase (MAT). After decarboxylation, SAm can donate the remaining propylamino moiety attached to its sulfonium ion to putrescine to form spermidine and methylthioadenosine (MTA) and to spermidine to form spermine and a second molecule of MTA. SAm donates its methyl group in a large variety of reactions catalyzed by dozens of methyltransferases (MTs), the most abundant in the liver being glycine-*N*-methyltransferase (GNMT). The SAH thus generated is hydrolyzed to form Hcy and adenosine through a reversible reaction catalyzed by SAH hydrolase. Hcy can be remethylated to form methionine by two enzymes: methionine synthase (MS) and betaine homocysteine methyltransferase (BHMT). In the liver, Hcy can also undergo the transsulfuration pathway to form cysteine via a two-step enzymatic process. In the presence of serine, Hcy is converted to cystathionine in a reaction catalyzed by cystathionine β -synthase (CBS). Cystathionine is then hydrolyzed by cystathionase to form cysteine, a precursor of the synthesis of glutathione (GSH). In tissues other than the liver, kidney, and pancreas, cystathionine is not significantly converted to GSH due to the lack of expression of one or more enzymes of the transsulfuration pathway. The expression of BHMT is also limited to the liver. All mammalian tissues convert Met into Hcy, via SAm and SAH, and remethylate Hcy into Met via the MS pathway. *Abbreviations:* THF, tetrahydrofolate; 5,10-MTHF, methylenetetrahydrofolate; 5-MTHF, methyltetrahydrofolate; Ser, serine; Gly, glycine; X, methyl acceptor molecule; X-CH₃, methylated molecule.

three isoforms of MAT (MATI, MATII, and MATIII) that are encoded by two genes (*MAT1A* and *MAT2A*). MATI and MATIII are tetrameric and dimeric forms, respectively, of the same subunit (α_1) encoded by *MAT1A*, whereas the MATII isoform is a tetramer of a different subunit (α_2) encoded by *MAT2A*. A third gene, *MAT2 β* encodes for a β subunit that regulates the activity of MATII (lowering the K_m and K_i for methionine and SAm, respectively) but not of MATI or MATIII (2). Adult differentiated liver expresses *MAT1A*, whereas extrahepatic tissues and fetal liver express *MAT2A*. *MAT1A* expression is silenced in HCC. It is an intriguing question why there are three different MAT isoforms in the liver. The predominant liver form, MATIII, has lower affinity for its substrates, a hysteric response to methionine (a hysteric behavior, defined as a slow response to changes in substrate binding, has been described for many important enzymes in metabolic regulation), and higher V_{max} , contrasting with the other two enzymes. On the basis of the differential properties of hepatic MAT isoforms, it has been postulated that MATIII is the truly liver-specific isoform. Under normal conditions, MATI would, as MATII outside the liver, synthesize most of the SAm required by the hepatic cells. However, after an increase in methionine concentration, that is, after a protein-rich meal, conversion to the high-activity MATIII would occur and methionine excess will be eliminated (Fig. 2). This will lead to accumulation of SAm and activation of glycine *N*-methyltransferase (GNMT), the main enzyme involved in hepatic SAm catabolism. Consequently, the excess of SAm will be eliminated and converted to homocysteine via SAH. Once formed, the excess of homocysteine will be used for the synthesis of cysteine and α -ketobutyrate as a result of its transsulfuration. This pathway involves two enzymes: cystathionine β -synthase (CBS), that is activated by SAm, and cystathionase. Cysteine is then utilized for the synthesis of GSH as well as other sulfur-containing molecules such as taurine, while α -ketobutyrate penetrates the mitochondria where it is decarboxylated to carbon dioxide and propionyl CoA. Because SAm is an inhibitor of 5,10-methylene-tetrahydrofolate-reductase (MTHFR), this will prevent the regeneration of methionine after a load of this amino acid. At the mRNA level, SAm maintains *MAT1A* and *GNMT* expression while inhibiting *MAT2A* expression. This modulation by SAm of both the flux of methionine into the transsulfuration pathway and the regeneration of methionine maximizes the production of cysteine and α -ketobutyrate, and consequently of ATP, after a methionine load minimizing the regeneration of this amino acid (oxidative methionine metabolism).

ALTERED SAm METABOLISM AND DISEASE

Altered SAm Metabolism in Liver Disease

Accumulating evidence supports the importance of maintaining normal SAm level in mammalian liver, as both chronic deficiency and excess lead to liver injury, steatosis, and development of hepatocellular carcinoma (HCC) (2,3). Majority of the patients with cirrhosis have impaired SAm biosynthesis because of lower *MAT1A* mRNA levels and inactivation of MATI/III (4,5). However, patients with *GNMT* mutations have been identified and they also

have evidence of liver injury (6). In mice, loss of GNMT results in supraphysiological levels of hepatic SAmE and aberrant methylation (7). The molecular mechanisms responsible for injury and HCC formation are different in *MAT1A* and *GNMT* knockout mice but these findings illustrate the importance of keeping SAmE level within a certain range within the cell.

In contrast to normal nonproliferating (differentiated) hepatocytes, which rely primarily on MATI/III to generate SAmE and maintain methionine homeostasis, embryonic and proliferating adult hepatocytes as well as liver cancer cells instead rely on MATII to synthesize SAmE (2). Liver cancer cells often have very low levels of *GNMT* and *CBS* expression and increased expression of *MAT2 β* , which, as mentioned earlier, lowers the K_m for methionine and the K_i for SAmE of MATII. Consequently, proliferating hepatocytes and hepatoma cells tend to utilize methionine into protein synthesis regardless of whether methionine is present in high or low amounts and to divert most homocysteine away from the transsulfuration pathway by regenerating methionine and tetrahydrofolate (THF) (aerobic methionine metabolism). *MAT2A/MAT2 β* -expressing hepatoma cells have lower SAmE levels than cells expressing *MAT1A*, which also favors the regeneration of methionine and THF. From these results, it becomes evident that proliferating hepatocytes and hepatoma cells do not tolerate well high SAmE levels for converting methionine via the transsulfuration pathway to cysteine and α -ketobutyrate.

The finding that *MAT1A*, *GNMT*, *MTHFR*, and *CBS* knockout mice spontaneously develop fatty liver (steatosis) and, in the case of *MAT1A*- and *GNMT*-deficient animals, HCC also (3) demonstrates the synchronization of methionine metabolism with lipid metabolism and hepatocyte growth.

The medical implications of these observations are obvious, since the majority of cirrhotic patients, independent of the etiology of their disease, have impaired metabolism of methionine and reduced hepatic SAmE synthesis and are predisposed to develop HCC (4,5); and individuals with *GNMT* mutations that lead to abnormal SAmE catabolism develop liver injury (6). Moreover, the observation that genetic polymorphisms that associate with reduced *MTHFR* activity and increased thymidylate synthase activity, both of which are essential in minimizing uracyl misincorporation into DNA, may protect against the development of HCC in humans (8) further supports that this synchronization may be an adaptive mechanism that is programmed to fit the specific needs of hepatocytes, and that alterations in the appropriate balance between methionine metabolism and proliferation may be at the origin of the association of cancer with fatty liver disease.

An explanation for these observations connecting methionine metabolism with the development of fatty liver and HCC has remained elusive because the association of SAmE with lipid metabolism and hepatocyte proliferation is, at first glance, not intuitive. During the past years, a signaling pathway that senses cellular SAmE content and that involves AMP-activated protein kinase (AMPK) has been identified to operate in hepatocytes (9,10). AMPK is a serine/threonine protein kinase that plays a crucial role in the regulation of energy home-

ostasis and cell proliferation. AMPK is activated by stress conditions leading to an increase in the AMP/ATP ratio, such as during liver regeneration. Once activated, AMPK shuts down anabolic pathways that mediate the synthesis of proteins, fatty acids, lipids, cholesterol, and glycogen and stimulates catabolic pathways such as lipid oxidation and glucose uptake restoring ATP levels and keeping the cellular energy balance. The finding that in the liver AMPK activity is tightly regulated by SAmE (9,10) has provided a first link between methionine metabolism, lipid metabolism, and cell proliferation. Moreover, excess SAmE can induce aberrant methylation of DNA and histones, resulting in epigenetic modulation of critical carcinogenic pathways (7). Finally, there is evidence indicating that SAmE regulates proteolysis, widening its spectrum of action. In hepatocytes, the protein levels of prohibitin 1 (PHB1) (11), the apurinic/apyrimidinic endonuclease (APEX1) (12), and the dual specificity MAPK phosphatase (DUSP1) (13) are stabilized by SAmE through a process that may involve proteasome inactivation. PHB1 is a chaperone-like protein involved in mitochondrial function, APEX1 is a key protein involved in DNA repair and genome stability, and DUSP1 is a member of a family of mitogen-activated protein kinases (MAPKs) phosphatases, which simultaneously dephosphorylates both serine/threonine and tyrosine residues.

SAmE Deficiency in Depression

Major depression has been associated with a deficiency in methyl groups (folate, vitamin B₁₂, and SAmE) (14,15). Thus, depressed patients often have low plasma folate and vitamin B₁₂ and reduced SAmE content in the CSF. Moreover, patients with low plasma folate appear to respond less well to antidepressants. The mechanism by which low SAmE concentrations may contribute to the appearance and evolution of depression is, however, not well known. SAmE-dependent methylation reactions are involved in the synthesis and inactivation of neurotransmitters, such as noradrenaline, adrenaline, dopamine, serotonin, and histamine; and the administration of drugs that stimulate dopamine synthesis, such as L-dihydroxyphenylalanine, cause a marked decrease in SAmE concentration in rat brain and in plasma and CSF in humans. Moreover, various drugs that interfere with monoaminergic neurotransmission, such as imipramine and desipramine, reduce brain SAmE content in mice (14,15). As in the liver, abnormal SAmE levels may contribute to depression through perturbation of multiple metabolic pathways in the brain. Interestingly, alterations in methionine metabolism that lead to a decrease in the brain SAmE/SAH ratio associate with reduced leucine carboxyl methyltransferase-1 (LCMT-1) and phosphoprotein phosphatase 2A_B (PP2A_B) subunit expression, and accumulation of unmethylated PP2A (16). PP2A enzymes exist as heterotrimeric complexes consisting of catalytic (PP2A_C), structural (PP2A_A), and regulatory (PP2A_B) subunits (17). Different PP2A_B subunits have been described that determine the substrate specificity of the enzyme. PP2A_C subunit is methylated by SAmE-dependent LCMT-1 and demethylated by a specific phosphoprotein phosphatase methylesterase (PME1). PP2A_C methylation has no effect on PP2A activity but has a crucial role in the recruitment of specific PP2A_B subunits

to the PP2A_{A,B} complex and therefore PP2A substrate specificity. Downregulation of LCMT-1 and PP2A_B and accumulation of unmethylated PP2A are associated with enhanced Tau phosphorylation and neuronal cell death (16).

INDICATIONS AND USAGE

SAMe Treatment in Animal Models of Liver Disease

The importance of the metabolism of methyl groups in general, and SAMe in particular, to normal hepatic physiology, coupled with the convincing body of evidence linking abnormal SAMe content with the developmental of experimental and human liver disease, led to the examination of the effect of SAMe supplementation in various animal models of liver disease. SAMe administration to alcohol-fed rats and baboons reduced GSH depletion and liver damage (2,18). SAMe improved survival in animal models of galactosamine-, acetaminophen- and thioacetamide-induced hepatotoxicity, and in ischemia-reperfusion-induced liver injury (18). SAMe treatment also diminished liver fibrosis in rats treated with carbon tetrachloride (18) and reduced neoplastic hepatic nodules in animal models of HCC (19,20). Similar to the liver, SAMe can block mitogen-induced growth and induce apoptosis in human colon cancer cells (21,22).

SAMe Treatment in Human Diseases

SAMe has been used in humans for the past 20 years for the treatment of osteoarthritis, depression, and liver disease. In 2002, the Agency for Healthcare Research and Quality (AHRQ) reviewed 102 individual clinical trials of SAMe (23). Of these 102 studies, 47 focused on depression, 14 focused on osteoarthritis, and 41 focused on liver disease. Of the 41 studies in liver disease, 9 were for cholestasis of pregnancy, 12 were for other causes of cholestasis, 7 were for cirrhosis, 8 were for chronic hepatitis, and 4 were for various other chronic liver diseases.

Pharmacokinetics of SAMe

Orally administered SAMe has low bioavailability, presumably because of a significant first-pass effect (degradation in the gastrointestinal tract) and rapid hepatic metabolism. Peak plasma concentrations obtained with an enteric-coated tablet formulation are dose related, with peak plasma concentrations of 0.5 to 1 mg/L achieved three to five hours after single doses ranging from 400 to 1000 mg (23). Peak levels decline to baseline within 24 hours. One study showed a significant gender difference in bioavailability, with women showing three- to sixfold greater peak plasma values than men (23). Plasma-protein binding of SAMe is no more than 5%. SAMe crosses the blood-brain barrier, with slow accumulation in the CSF. Unmetabolized SAMe is excreted in urine and feces.

Parenterally administered SAMe has much higher bioavailability. However, this form is currently not approved for use in the United States.

SAMe Treatment in Liver Diseases

Out of the 41 studies in liver disease analyzed by AHRQ, 8 studies were included in a meta-analysis of the efficacy of SAMe to relieve pruritus and decrease elevated

serum bilirubin levels associated with cholestasis of pregnancy (23). Compared with placebo, treatment with SAMe was associated with a significant decrease in pruritus and serum bilirubin levels. Similar results were obtained when six studies were included in a meta-analysis of the efficacy of SAMe to relieve pruritus and decrease bilirubin levels associated with cholestasis caused by various liver diseases other than pregnancy.

In 2001, the Cochrane Hepato-Biliary Group analyzed eight clinical trials of SAMe treatment of alcoholic liver disease including 330 patients (24). This meta-analysis found SAMe decreased total mortality [odds ratio (OR) 0.53, 95% confidence interval (CI): 0.22 to 1.29] and liver-related mortality (OR 0.63, 95% CI: 0.25 to 1.58). However, because many of the studies were small and the quality of the studies varied greatly, the Cochrane Group concluded, "SAMe should not be used for alcoholic liver disease outside randomized clinical trials" (24). The AHRQ reached a similar conclusion, "For liver conditions other than cholestasis additional smaller trials should be conducted to ascertain which patient populations would benefit more from SAMe, and what interventions (dose and route of administration) are most effective" (23). The Cochrane Hepato-Biliary Group also concluded that only one trial including 123 patients with alcoholic cirrhosis used adequate methodology and reported clearly on mortality and liver transplantation. In this study (25), mortality decreased from 30% in the placebo group to 16% in the SAMe group ($P = 0.077$). When patients with more advanced cirrhosis (Child score C) were excluded from the analysis (eight patients), the mortality was significantly less in the SAMe group (12%) as compared with the placebo group (25%, $P = 0.025$). In this study, 1200 mg/day was administered orally. Unfortunately, new controlled prospective double-blind multicenter studies on the benefits of SAMe for liver diseases are lacking.

SAMe Treatment in Depression

Out of the 39 studies in depression analyzed by the AHRQ, 28 studies were included in a meta-analysis of the efficacy of SAMe to decrease symptoms of depression (23). Compared with placebo, treatment with SAMe was associated with an improvement of approximately six points in the score of the Hamilton Rating Scale for Depression measured at three weeks (95% CI: 2.2 to 9.0). This degree of improvement was statistically as well as clinically significant. However, compared with the treatment with conventional antidepressant pharmacology, treatment with SAMe was not associated with a statistically significant difference in outcomes. With respect to depression, the AHRQ report concluded, "Good dose-escalation studies have not been performed using the oral formulation of SAMe for depression" (23). The AHRQ report also concluded, that "Additional smaller clinical trials of an exploratory nature should be conducted to investigate uses of SAMe to decrease the latency of effectiveness of conventional antidepressants and to treat of postpartum depression" (23). Unfortunately, these clinical studies are still lacking.

SAMe Treatment in Osteoarthritis

Out of the 13 studies in osteoarthritis analyzed by the AHRQ, 10 studies were included in a meta-analysis of

the efficacy of SAME to decrease pain of osteoarthritis (23). Compared with placebo, one large randomized clinical trial showed a decrease in the pain of osteoarthritis with SAME treatment. Compared with the treatment with nonsteroidal anti-inflammatory medications, treatment with oral SAME was associated with fewer adverse effects while comparable in reducing pain and improving functional limitation. In 2009, the Cochrane Osteoarthritis Group analyzed 4 clinical trials including 656 patients, all comparing SAME with placebo (26). The Cochrane Group concluded, "The effects of SAME on both pain and function may be potentially clinically relevant and, although effects are expected to be small, deserve further clinical evaluation in adequately sized randomized, parallel-group trials in patients with knee or hip osteoarthritis. Meanwhile, routine use of SAME should not be advised" (26).

Adverse Effects

The risks of SAME are minimal. SAME has been used in Europe for more than 20 years and is available under prescription in Italy, Germany, United Kingdom, and Canada, and over the counter as a dietary supplement in the United States, China, Russia, and India. The most common side effects of SAME are nausea and gastrointestinal disturbance, which occurs in less than 15% of treated subjects. Recently, SAME administration to mice treated with cisplatin has been found to increase renal dysfunction (27). Whether SAME increases cisplatin renal toxicity in humans is not known.

Interactions with Herbs, Supplements, and Drugs

Theoretically, SAME might increase the effects and adverse effects of products that increase serotonin levels, which include herbs and supplements such as Hawaiian Baby Woodrose, St. John's wort, and L-tryptophan, as well as drugs that have serotonergic effects. These drugs include tramadol (Ultram), pentazocine (Talwin), clomipramine (Anafranil), fluoxetine (Prozac), paroxetine (Paxil), sertraline (Zoloft), amitriptyline (Elavil), and many others. It is also recommended that SAME should be avoided in patients taking monoamine oxidase inhibitors or within two weeks of discontinuing such a medication.

CONCLUSIONS

Although evidence linking abnormal SAME content with the development of experimental and human liver disease is very convincing, the results of clinical trials of SAME treatment of liver disease are not conclusive. Consequently, SAME should not be used outside clinical trials for the treatment of liver conditions other than cholestasis. A new clinical study enrolling a larger number of patients should be carried out to confirm that SAME decreases mortality in alcoholic liver cirrhosis. This is important because if SAME improves survival, SAME will become the only available treatment for patients with alcoholic liver cirrhosis.

Although depression has been associated with a deficiency in SAME, it is not yet clear whether this is a consequence or the cause of depression. To clarify this point, more basic research and the development of new exper-

imental models are needed. Clinical trials indicate that SAME treatment is associated with an improvement of depression. Dose studies using oral SAME should be performed to determine the best dose to be used in depression. New studies should also be carried out where the efficacy of SAME is compared with that of conventional antidepressants.

With respect to osteoarthritis, at present there is no evidence associating a deficiency in SAME with the appearance of the disease. Moreover, the efficacy of SAME in the treatment of osteoarthritis is also not convincing at present.

Aloe Vera

Santiago Rodriguez, Steven Dentali, and Devon Powell

INTRODUCTION

Aloe vera is one of the oldest known medicinal herbs with a history of use that spans thousands of years. Today, aloe vera is cultivated and used in a large variety of commercial preparations. It is an economic driver in the food, dietary supplement, and personal care industries worldwide. The two main commercial materials derived from aloe vera are aloe vera juice and aloe latex. Aloe vera juice is used for various dietary, cosmetic, and medical purposes such as burn treatment, wound healing, and skincare. It is available in several forms including liquid juice, juice powder, and concentrates. Aloe latex was formerly recognized as an over-the-counter (OTC) laxative drug in the United States. It has seen limited use in dietary supplements as a laxative and in the personal care industry as a skin lightener.

Confusion among consumers, researchers, and regulatory bodies has arisen from the fact that products from aloe latex are often referred to as simply “aloe” or “aloe juice” (including in pharmacopoeias and other official documents around the world), which is physically, chemically, and biologically distinct from products made from the charcoal filtered whole leaf or inner leaf aloe vera juice. These latex-free juice products represent the vast majority of aloe products on the market. Regardless, the prominence of, interest in, and use of aloe vera products for centuries attests to the plant’s myriad value and benefits.

BACKGROUND

Aloe vera (L.) Burm. f. is one of more than 400 known *Aloe* species in the Asphodelaceae family, though it is sometimes classified in Aloaceae. Because most aloe species are indigenous to Africa, it is most likely that aloe vera also originated from that continent. However, because of its now worldwide cultivation, its origin is difficult to establish. Linnaeus classified aloe vera as the “true aloe” hence the name “vera,” meaning true in Latin. Although it has also been known as *Aloe barbadensis*, *Aloe chinensis*, *Aloe indica*, *Aloe vulgaris*, and others, *A. vera* (L.) Burm. f. has precedence (1). Its standardized common name is “aloe vera” though it has also been called Barbados aloe, Curaçao aloe, true aloe, West Indian aloe, Ghrita kumari, or simply aloe (2).

The plant is cactus-like in appearance with succulent leaves that grow in a spiral form from a basal rosette (Fig. 1). An inflorescence is produced annually (typically December through March) with yellow flowers in a trident configuration from a single central stalk with many

flowers in each of the three branches. Aloe vera does not normally reproduce from seeds but from offshoots often called “pups” that grow out from the mother plant. When the green outer rind of the leaves is cut or damaged, a bitter yellow exudate from pericyclic tubules located between the outer rind and the inner leaf is released. This sap is commonly referred to as “aloe latex” (3) and contains several anthraquinone glycosides that have powerful stimulant laxative properties.

When the rind is completely removed, a semitransparent, semicrystalline gel-like layer composed of large thin-walled parenchyma cells is revealed. This inner leaf material is often called “aloe gel,” or “inner leaf fillet,” because of its similarity in shape to a fish fillet. When crushed, it produces a very viscous fluid usually containing approximately 98.5% water. The solids are composed mainly of polysaccharides and other carbohydrates, pectin, and organic acids.

As mentioned earlier, aloe latex-derived products are used as a laxative agent and the processed leaf or inner leaf is often employed topically for the treatment of burns and injury. More recent applications range from skin-moisturizing agents to the management of cancers in animals to impregnation in articles of clothing and mattresses for its softening and moisturizing properties. Aloe vera juice is also orally ingested to manage digestive ailments and for its immune-modulating activities and is sold worldwide in beverage form as a food-based drink product available in various flavors. Aloe vera is also used widely in Ayurvedic medicine (4).

CULTIVATION

Aloe vera is cultivated in subtropical regions around the globe for commercial use and is widely grown by indoor and outdoor plant enthusiasts as an ornamental plant because of its hardiness and beauty. The species is resistant to most insect pests and needs very little maintenance or care to flourish, given appropriate temperature conditions (5).

Because of its very low inner leaf solid content of 0.5% to 1.5%, aloe vera plants are highly susceptible to freezing, which causes extensive damage, even killing them when the temperature falls below 32°F. For this reason, commercial cultivations are typically carried out in warm weather areas (USDA zones 8–11). *Aloe vera* is the most cultivated species of the various *Aloe* species because it produces the largest, thickest leaves and therefore yields the greatest amount of juice. It is cultivated extensively in

Figure 1 Aloe vera flowering. Source: Courtesy of Santiago Rodríguez, Houston, Texas.

Mexico, the Dominican Republic and other Caribbean Islands, Central America, Venezuela, the southern border areas of Texas, New Mexico, Arizona, and California, as well as Tanzania, Uganda, South Africa, Australia, Southern China, Thailand, and India. Some small acreage is also present in the Canary Islands as well as Southern Spain and Southern Italy and recently new commercial operations have been proposed in areas such as Greece, Iran, Pakistan, and other countries in the Middle East.

Aloe vera prefers very well-drained soils, such as sandy loam, but can grow in almost any type of soil. Although aloe vera is naturally adapted to survive in very dry climates, water must be supplied to the plant year-round in order to keep the leaves succulent enough for a good commercial juice yield. Aloe vera is typically planted at a density of 10,000 plants per acre yielding approximately 40 metric tons of leaves per year. Commercial growers should not make the mistake of planting these large plants too densely. The suggested row spacing is a standard, 42-inch-wide row with approximately 60 cm of spacing between plants.

Harvesting usually begins two years after planting. The plants are harvested year-round by carefully remov-

ing most of the outer, lower, older leaves. Typically one to four leaves are removed at a time per plant per harvest. This way it is possible to obtain three to six harvests in a year depending on how many leaves are collected from each plant at harvest.

Cultivation practices for the industrial production of aloe extracts made from the yellow latex sap are radically different from those used to grow aloe vera for juice. In the case of sap production, plants are not irrigated and are grown in arid regions. The leaves turn brown and thin under these conditions but when cut produce the maximum amount of an anthraquinone glycoside-rich latex, the principal constituents of which are the compounds known as "aloins A and B." The sap exudates are collected and further processed to produce two main products, aloe latex concentrate also known as "aloin paste" and a product commercially known as "aloin spray dried."

DESCRIPTION

The leaf of aloe vera is normally described as consisting of three major parts that are used in commercial products: the outer mesophyll (rind or cuticle), the interior parenchyma (inner leaf, gel or gel fillet, inner gel, inner leaf gel fillet), and the aloe latex (sap, bitter element, yellow sap, yellow latex). Researchers, raw material manufacturers, and finished goods manufacturers have utilized all three plant parts separately or in combination for aloe vera research and in the formulation of consumer products.

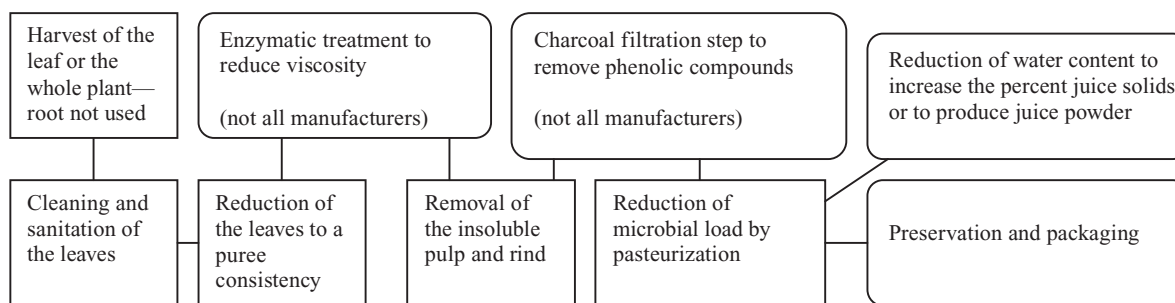

Outer Mesophyll (Rind)

Aloe vera rind or cuticle is the site of photosynthesis and primarily consists of cellulose, monosaccharides, water soluble and insoluble carbohydrates, chlorophyll, amino acids, proteins, and lipids.

Interior Parenchyma (Inner Leaf)

Aloe vera inner leaf is the colorless, mucilaginous parenchyma of the aloe vera plant leaf consisting of water, monosaccharides, water-soluble carbohydrates, water-soluble polysaccharides, and water-insoluble fibrous pulp. The compound β -(1-4)-acetylated mannan, a polysaccharide also known as "acemannan" or "acetylated polymannose," is widely considered to be the biologically most important component of the inner leaf. After removal of fibrous pulp from the inner leaf, the resulting juice contains about 0.5% to 1.5% solids.

Histological examination of aloe vera inner leaf pulp has shown it to be composed of large cells made up of 16% cell walls, about 1% microparticles, and 83% of a viscous gel on a dried weight basis. The carbohydrate portion of each of these components was distinct, with the cell walls composed of 34% galacturonic acid (an unusually high level), the microparticles composed of galactose-rich polysaccharides, and the liquid gel contained mannan (6). These findings showed that different pulp structures are associated with different polysaccharides and may therefore confer different biological activities.

Flowchart 1 Aloe vera whole leaf processing.

Aloe Latex (Aloe Sap, Aloe Bitters)

Aloe latex is a yellow-green bitter exudate that contains the anthraquinone glycosides aloins A and B, formerly known as “barbaloin” and “isobarbaloin,” respectively. The aloin content of aloe latex changes with the season and the age of the leaf but usually makes up 10% to 25% of the dried latex by weight. Products made from aloe latex have been used historically as a laxative. The source plant is most commonly *Aloe ferox* from Africa or Argentina.

COMMERCIAL RAW MATERIAL PROCESSING

Aloe Vera Juice

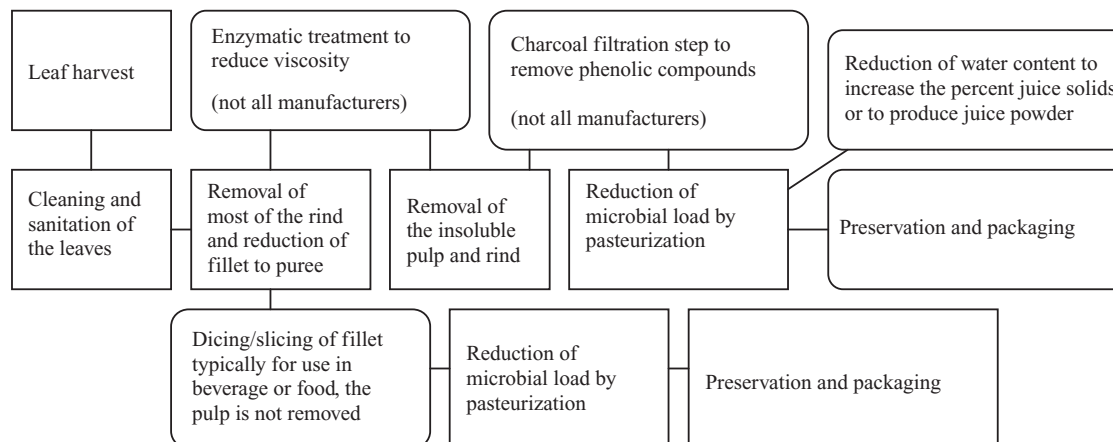

Aloe vera juice can be manufactured from raw leaves in two ways—from the entire leaf or from only the inner leaf material. In both cases, the leaves are first processed to remove the side thorns and tips. For aloe vera juice made from the entire leaf, the leaves are macerated in a grinder into what is commonly called “guacamole” and then further processed by enzymatic treatment (usually with cellulase) to break up cell walls and then charcoal filtered to remove anthraquinones and other phenolic constituents. The resulting aloe vera juice is commonly referred to as “filtered aloe vera juice” or “purified whole leaf aloe vera juice.” See flowchart 1 for more detail.

When creating juice from only the inner leaf material, the inner leaf is separated from the outer rind either manually with a knife or by machine and then washed to rinse away any aloe latex present. The remaining material is crushed and further processed to produce the aloe vera juice. See flowchart 2 for more detail.

At this stage, regardless of starting material, the now-processed aloe vera juice is typically called “single-strength.” The juice from the leaf or inner leaf can also be further processed to produce concentrates and powders and are often spray or freeze dried. Some heat is usually applied in the industrial production of aloe vera juice to deactivate enzymes that would break down the mannans into oligosaccharides and simple sugars. Heating also serves to control the normal microbial load present on the plant. Enzymatic treatment can be used to further break down cell walls, with filtration removing any remaining insoluble fiber. The resulting filtered juice contains all the major groups of components from the original aloe vera inner leaf.

Aloin-Rich Materials

The commercial production of aloin-rich materials starts with the specialized cultivation practices mentioned earlier. In contrast to aloe juice production, the leaves are

Flowchart 2 Aloe vera inner leaf processing.

**Figure 2** Structures of Aloin A & B.

gathered and the whole plant is cut at the base, producing a transverse cut on all the leaves of the plant at the same time. These leaves are placed in a V-shaped collection device and the aloin-rich sap is allowed to drain. The resulting yellow sap is then concentrated by applying heat until it becomes viscous and forms a solid upon cooling. This aloin paste product contains approximately 25% of the anthraquinone glycosides aloins A and B (Fig. 2). A more sophisticated production method takes the yellow sap, precipitates the resins by adding acid, and concentrates the soluble fraction under vacuum at reduced temperature. The concentrate is then spray dried to produce "spray-dried aloin," which typically contains about 50% aloins. Aloin-rich aloe extracts have been used worldwide mostly in laxative preparations though it has other uses including as a bitter flavoring agent, especially in the wine industry.

Acemannan

Mannan is a generic name for polysaccharides that are polymers of the sugar mannose. In aloe vera juice, the mannose moieties are connected by β -(1-4) linkages, which are partially substituted with acetate units and with galactose-rich side chains on the mannose backbone. This β -(1,4)-acetylated-polymannose material is also known by other names such as "aloverose" and "acemannan"; the latter is also a name given to a proprietary substance covered by many patents (7) and has been assigned as a generic name by the United States Adopted Names Council (8). It is based on the chemical name as it refers to the acetylated *mannan* found in all aloe vera inner leaf fillets (Fig. 3).

Acemannan is not sold as a pure material; however, many commercial products contain varying amounts of it depending on the processing of the aloe vera leaf as men-

tioned earlier. The therapeutic properties of aloe vera juice have been largely attributed to its polysaccharide component and acemannan in particular. This high-molecular-weight material is perhaps the most studied component of the aloe vera plant aside from the anthraquinone glycosides. Many industrial methods have been developed to stabilize the aloe vera juice and prevent polysaccharide degradation. Drying the juice at temperatures over 60°C has been shown to cause deleterious changes in acemannan and also pectin from the cell walls (9).

ANALYSIS OF COMMERCIAL PRODUCTS

Analysis of 32 commercial products showed wide variations in polysaccharide content when compared by molecular weight (10), which was attributed to different manufacturing procedures. A second study of nine commercial powders used a method that hydrolyzed the mannan into mannose as a rapid way to measure the total polysaccharide content in the powder. One sample was found to have an abnormally high concentration of free glucose, four showed signs of spoilage, and all but three were found to have low levels of polymannose present (11). Both studies found all samples to have a significantly lower amount of aloins than the raw unwashed inner leaf fillet, with a high of 16 ppm of aloin A found in one sample in one of the studies. Because of the widespread use of aloe vera juice in personal care products, a voluntary industry limit of 50 ppm aloin content for use in cosmetics as a topical agent has been established (12).

PRECLINICAL STUDIES

General

Many of the biological properties of aloe vera have been attributed to acemannan. This compound has been studied

**Figure 3** Partial molecular model of acemannan [β -(1,4)-acetylated-polymannose]. Source: Courtesy of Santiago Rodriguez, Houston, Texas.

Figure 4 Aloe vera plant. Source: Courtesy of Devon Powell, Columbia, Maryland.

for its ability to effect changes in a mouse macrophage cell line and was found to stimulate cytokine production, nitric oxide release, surface molecule expression, and cause changes to cell morphology. This, coupled with the finding that the effect on cytokine production was dose dependent (13), suggests that acemannan may function in part through macrophage activation.

The dermatological activities of aloe vera were investigated in a systematic review that extracted data from 40 studies in a predetermined standardized manner (14). Orally administered to mice, it was found to be effective in promoting wound healing and reducing the incidence of tumors and leishmania parasites by greater than 90% in selected tissues. Its antiviral and antimicrobial properties as well as positive effects on inflammation, frostbite, and burns were reported. Topical application was found not to protect against sunburn in this review. Clinical effectiveness for the use of aloe vera for dermatological conditions was not thought to be sufficiently explored.

Another review examined purported biological properties of aloe vera leaf juice, namely promotion of wound healing, and antifungal, antidiabetic, anti-inflammatory, anticancer, immunomodulatory, and gastroprotective properties and focused on more recently discovered effects and applications such as the ability of aloe vera juice to increase the bioavailability of coadministered compounds and to enhance skin permeability (15).

Wound Healing

The wound healing activity of topical and oral aloe vera was studied in rodent models of anti-inflammatory effects and wound healing (16). Both supernatant and precipitate fractions of a 50% ethanol extract of aloe vera decreased inflammation but only the high-molecular-weight precipitate

fraction demonstrated wound healing activity (17), suggesting that more than one aloe compound could be useful in treating both inflammation and wounds.

Skin Moisturizing

Aloe vera applied topically has a moisturizing effect on skin (18) and has been used for this purpose and as a conditioning agent.

Antidiabetic Activity

Rodent studies have shown blood glucose regulating activity of an aloe vera alcoholic extract (19) and processed aloe vera inner leaf juice (20), suggesting its utility in treating non-insulin-dependent diabetes.

Antitumor Activity

Acemannan has shown significant antitumor activity via immune system activation. In a mouse model, IP injection of acemannan at the time of implantation of sarcoma cells resulted in a 40% survival rate in the treated animals versus 0% of the controls, most likely because of the production of monokines from macrophage peritoneal stimulation. The data suggested that this acemannan-stimulated synthesis "resulted in the initiation of immune attack, necrosis, and regression of implanted sarcomas in mice" (21). A study involving acemannan treatment as an adjunct to surgery and radiation in confirmed fibrosarcoma in dogs and cats showed tumor shrinkage in one-third of the animals after four to seven weeks of treatment administered by intraperitoneal and intralesional injections (22). An earlier study by the same group showed similar results (23).

Studies on Aloin-Rich Materials

Aloin-rich extracts derived from aloe latex belong to the stimulant laxatives drug class. Aloins are inactive until deglycosylated by intestinal flora to form aloe-emodin, the putative active compound (24). Their mechanism of action is believed to involve increasing peristalsis and water accumulation in the colon (25). Aloe latex has been subjected to a human clinical trial as a laxative in combination with other ingredients (26).

The potential toxicities of aloin and its metabolites are not well established though studies have shown it does not promote colon cancer in a mouse model (27) and induces cell changes that could be a sign of anticancer activity (28). Selective activity against certain cancers has also been demonstrated by aloe-emodin, a metabolite of aloins A and B (29,30).

CLINICAL STUDIES

Wound Healing

Although one study showed a delay in healing wound complications after cesarean delivery or gynecological surgery following treatment with "aloe vera dermal wound gel" (31), another recorded a 6-day statistically significant reduction (from 18 to 12 days) in the healing time of partial thickness burns. A systematic review of the literature for the use of topical aloe vera in treating burn wounds included four controlled clinical trials involving 371 patients. A meta-analysis based on the time for healing showed almost nine fewer days required for

the aloe vera–treated group over the controls (32). No specific conclusions could be drawn because of the difference in preparations and outcome measures. Further studies with well-characterized materials were called for by the authors as cumulative evidence tended to support the use of aloe vera for the treatment of first- and second-degree burns. A bioadhesive patch of an aloe vera preparation was evaluated in an open uncontrolled trial for the management of mouth ulcers in children with apparent good results (33).

Ulcerative Colitis and Irritable Bowel Syndrome (IBS)

Ulcerative colitis is caused by a dysfunction of the immune system (34). A 2004 clinical trial involving 44 patients with mild or moderately active ulcerative colitis compared 100 mL twice-daily oral aloe vera juice treatment with placebo for four weeks. The aloe vera–consuming patients showed positive clinical responses more often than placebo. Clinical remission was seen in 30% of the active group, clinical improvement in 37%, and a clinical response in 47% of patients compared with 7%, 7%, and 14% in the placebo group, respectively. Histological scores and the Simple Clinical Colitis Activity Index did not change in the placebo group but decreased significantly for those who consumed aloe vera. No significant differences were seen between the two groups with regard to laboratory values or sigmoidoscopic scores (35).

A human clinical study using aloe vera for treatment of irritable bowel in refractory secondary care patients failed to show a benefit, though the authors could not rule out that diarrhea-predominant patients were helped (36).

Antidiabetic Activity

Aloe dried sap has demonstrated hypoglycemic activity in a study involving five patients with non-insulin-dependent diabetes (37).

Antitumor Activity

A preliminary clinical trial on the use of orally administered “aloe vera tincture” for untreatable metastatic solid tumor patients with and without melatonin treatment showed a significantly higher percentage of nonprogressing patients in the group that received the aloe treatment (50% vs. 27%, $P < 0.05$) (38). Another human trial on 240 patients treated with *Aloe aborescens* (used because of purported immunostimulating activity from this plant owing to its acemannan component) suggested that oral aloe therapy may be a successful adjunct to chemotherapy in patients with metastatic solid tumors. Tumor regression rate and survival time were improved in this study (39). No conclusions can be drawn from this study because details on characterization of the test material were not provided.

SAFETY

A four-week subacute oral toxicity study in mice administered a freeze-dried aloe juice product reported no remarkable subacute toxic effects but did note a decrease in male kidney weights. The report also provided a review of several adverse reaction case studies associated

with aloe vera (40). They ranged from skin irritation from topical use to one report of acute hepatitis in a 73-year-old female taking oral aloe vera capsules for constipation. A second case of acute hepatitis involving a 26-year-old man who had been drinking “aloe vera tea” has also been reported (41).

The National Toxicology Program of the U.S. government nominated “aloe vera gel” for study in 1998 (42). No long-term carcinogenicity studies of aloe vera gel in animals were identified at that time. NTP subsequently chose to conduct a two-year carcinogenicity study on mice and rats with a “whole leaf extract” (43) that includes a considerable amount of latex aloins. The majority of aloe vera juice products intended for long-term internal use are either charcoal filtered whole leaf preparation or are made from washed inner leaf juice with aloin concentrations typically under 10 parts per million. The NTP report was still in progress at the time of publication of this chapter.

REGULATORY STATUS

United States

Aloe and aloin are present in the first approved food additives list published by the U.S. Food and Drug Administration in 1959. Although initially approved in the United States in 1975 as an OTC drug to treat chronic constipation, aloe latex is no longer approved for such use in the United States as of May 9, 2002 (44). Standard quality tests for aloe latex have been described in detail in many official pharmacopeias including the *United States Pharmacopeia*, *Japanese Pharmacopoeia*, and the *European Pharmacopoeia*, though, as mentioned in the introduction, these texts typically define aloe latex as simply “aloe” or incorrectly as “aloe juice.”

Aloe vera juice products can be labeled and marketed as dietary supplements. Aloe latex may also be used in dietary supplements in the United States with laxative or constipation claims as long as such claims are not for the treatment of chronic constipation.

Australia

Aloe vera inner leaf (called “aloe barbadensis”) is eligible for use as an active or excipient ingredient in Australia in “Listed” medicines in the Australian Register of Therapeutic Goods. Acemannan is approved as a component. Components are not approved as substances for use in their own right and can only be used in conjunction with an approved source.

Some aloe vera juice and juice concentrate beverages are viewed as “nontraditional foods” and not as “novel foods” and there are some listed medicines described as “aloe vera drinking gel” or as “aloe vera juice.”

Canada

Aloe vera inner leaf, when included as a Natural Health Product (NHP) active ingredient, requires premarket authorization and a product license number for OTC human use. Such products must comply with the minimum specifications outlined in the current NHPD Compendium of Monographs (45).

European Community

Aloe vera inner leaf was listed as “currently not on the priority list” in the inventory of herbal substances for assessment by the European Medicines Agency as of March 2009. There is an EU regulatory limit established for aloin content of 0.1 ppm in orally ingested products based on a flavoring regulation in which the aloin is defined as an added ingredient as opposed to naturally occurring. The International Aloe Science Council (IASC) (a trade association) has taken a position that these regulations are not applicable to aloe vera juice products.

Japan

Aloe vera juice is regulated as a food beverage product in Japan and is not to contain more than 0.60 mg/kg of benzoic acid. Various forms of aloe vera and extracts thereof are used as components of functional food products or in Foods for Specified Health Use such as in fortified waters and fermented yogurt drinks.

South Korea

Aloe products, known as “edible aloe concentrate” and “edible aloe gel,” are regulated as food products by the Korean Food and Drug Administration. Juice or concentrate from the inner leaf or dried and powdered inner leaf material containing not-less-than 30 mg/g of total aloe polysaccharides is able to carry the health claim of “smoothing the evacuation” on the basis of 20 to 30 mg delivered as aloe polysaccharides. Processed aloe vera leaf or concentrates thereof, after removal of the inedible parts, and containing 2.0 to 50 mg/g of anthraquinones (as anhydrous barbaloin), is permitted to make the same health claim at the specified daily intake. Aloe vera is also one of the four botanical ingredients allowed to make immune system enhancement claims in South Korea.

CONCLUSION

Of the 400 known species of aloe, *Aloe vera* is the most commonly used in commerce and is cultivated in many different areas of the world. The plant yields two raw materials for use in various consumer products including foods, dietary supplements, cosmetics, and drugs, namely aloe vera juice and aloe latex. Aloe vera juice can be made from processing either the entire leaf or only the inner leaf material. Aloe vera juice is often further processed into a powder or concentrate.

Preliminary scientific evidence suggests that aloe vera has therapeutic benefits; however, more studies need to be conducted to definitively demonstrate efficacy. Consumers should be aware and informed when buying aloe vera products; although there are many quality products on the market, there are also many products that may bring little or no benefit to the user. The IASC maintains a certification program using validated analytical methods to determine and ensure products displaying the IASC program seal contain aloe vera of a particular quality. It is recommended that consumers verify that products displaying the IASC seal are current participants in the IASC certification program.

Androstenedione

Benjamin Z. Leder

INTRODUCTION

Androstenedione (chemical name: 4-androstene-3,17-dione) is a steroid hormone produced primarily in the reproductive system and adrenal glands in men and women. It circulates in the bloodstream and is the immediate precursor to the potent anabolic/androgenic hormone testosterone in the steroid synthesis pathway. Despite this well-known physiological classification, as well as a growing body of evidence demonstrating that orally administered androstenedione is converted to more potent steroid hormones, the United States Food and Drug Administration originally classified the hormone as a “dietary supplement.” As such, it was available to the general public without a prescription and for nearly a decade could be easily purchased in health clubs, nutrition stores, and over the Internet. This over-the-counter availability of androstenedione came to an end when Food and Drug Administration banned its sale in early 2004. The ban was then codified with the passing of the 2004 Anabolic Steroid Control Act. This law reclassified androstenedione as an anabolic steroid and hence a controlled substance.

GENERAL DESCRIPTION

The original and seemingly contradictory classification of androstenedione as a dietary supplement was based on the definition set forth in the 1994 Dietary Supplement Health and Education Act (DSHEA). According to the DSHEA, a substance was defined as a dietary supplement if it was a “product (other than tobacco) intended to supplement the diet that bears or contains one or more of the following dietary ingredients: a vitamin, mineral, amino acid, herb or other botanical. . . or a concentrate, metabolite, constituent, extract, or combination of any ingredient described above.” Hence, because androstenedione could be synthesized from plant products, it fell under that umbrella. Furthermore, the DSHEA specified that the Department of Justice could not bring action to remove a product unless it was proven to pose “a significant or unreasonable risk of illness or injury” when used as directed. Not surprisingly, after the passing of the DSHEA, the use of dietary supplements increased dramatically. In fact, by 1999, the dietary supplement industry in the United States was generating annual sales of \$12 billion (1).

Initially, androstenedione use was primarily confined to athletes in strength and endurance-related sports, an interest that seems to have sprung from reports of

its use in the official East German Olympic athlete doping program. The event that most dramatically sparked widespread curiosity in androstenedione, however, was the media report that the St. Louis Cardinals baseball player Mark McGwire had used androstenedione in the 1999 season (during which he broke the record for most home runs in a season). The publicity that surrounded this supplement also prompted an increased interest in related “prohormones,” such as norandrostenedione and androstenediol. This then led to a proliferation of claims concerning the potential benefits of androstenedione use. Manufacturers credited these products not only with promoting muscle growth and improving athletic performance but also with increasing energy, libido, sexual performance, and general quality of life. Additionally, androstenedione was often packaged in combination with other substances as part of an intensive nutritional approach to performance enhancement. An example of such a combination is shown in Figure 1. Clearly, the use of androstenedione and related compounds during that time went well beyond the accumulation of data that could provide a rational basis for their use.

PROHORMONE FACTORS
4-Androstenedione: 100 mg
19-Nor-5-Androstenedione: 50 mg
5-Androstenediol: 50 mg
DHEA: 50 mg

GH/IGF FACTORS
L-Arginine Pyroglutamate: 2500 mg
L-Ornithine Alpha-Ketoglutarate: 1250 mg
Taurine: 750 mg
Colostrum: 250 mg

LH BOOSTER
Tribulus: 250 mg
Acetyl-L-Carnitine: 250 mg
L-Carnitine: 100 mg

DHT BLOCKERS
Saw Palmetto: 200 mg
Beta Sitosterol: 200 mg
Pygeum Africanum: 50 mg

ESTROGEN BLOCKERS
Kudzu: 100 mg
Chrysin: 250 mg

Figure 2 Androstenedione's relationship to other steroid hormones. Enzyme abbreviations: 3β-HSD, 3β-hydroxysteroid dehydrogenase; 17β-HSD, 17β-hydroxysteroid dehydrogenase.

BIOCHEMISTRY AND PHYSIOLOGY

Androstenedione is a steroid hormone that is produced primarily in the adrenals, testes, and ovaries. It is classified as a "weak androgen" because it binds to the body's receptor for androgen hormones in a much less potent fashion than classic anabolic/androgenic steroids such as testosterone (2). It is synthesized from the precursor hormone dehydroepiandrosterone (itself a dietary supplement) and is the direct precursor to testosterone. In normal physiological circumstances, androstenedione can also be converted to potent feminizing hormones such as estrone and estradiol (both members of the "estrogen" class of hormones). The relationship between androstenedione, other steroid hormones, and the enzymes involved in the conversion of androstenedione to testosterone and estrogens is shown in Figure 2.

Importantly, the enzymes that convert androstenedione to potent hormones such as testosterone and estradiol are active not only in endocrine glands but also in many peripheral body tissues such as muscle, bone, liver, and brain (3). Thus, if orally administered androstenedione has biological activity, it may act either directly or by conversion to these more potent agents.

ANDROSTENEDIONE USE

There were no precise data concerning the prevalence of androstenedione use in the general population during the time that it was widely available. Our best estimates were based on industry sales figures and extrapolations from data on classic anabolic/androgenic steroid use in specific populations. For example, in 1997, it was estimated that

4.9% of male and 2.4% of female adolescents in the United States had used illegal anabolic steroids (4). Because these substances were so readily available, there was concern that androstenedione use in this particularly susceptible population may have greatly exceeded these numbers. In fact, in a survey administered in five health clubs in Boston, Massachusetts, in 2001, 18% of men and 3% of women respondents admitted to using androstenedione or other adrenal hormone dietary supplements at least once. These percentages suggested that as many as 1.5 million U.S. health club members alone may have used these substances (5).

PHARMACOKINETICS AND HORMONAL EFFECTS OF ANDROSTENEDIONE IN MEN

Because so many of the claims that surrounded androstenedione were based on the premise that oral administration increases serum testosterone levels, it may be surprising to some that prior to 1999, there was only a single published study investigating the ability of orally administered androstenedione to be converted to more potent steroid hormones (6). In this study, two women were given a single dose of androstenedione, and the levels were subsequently measured over the next several hours. Since 1999, however, numerous small studies (mostly in men) have investigated the effects of the supplement (6–16). In general, these studies report that serum androstenedione levels increase dramatically after oral administration and thus confirm that a significant portion of the supplement is absorbed through the gastrointestinal tract after ingestion. However, the answer to the more important question, namely, whether it is then converted to more potent steroid hormones such as testosterone and estradiol, appears to be complex. In general, these studies suggest that the ability of oral androstenedione to increase estrogen and testosterone levels in men is dose dependent and is possibly related to the age of the study population as well. Specifically, the bulk of the research indicates that when androstenedione is administered to men in individual doses between 50 and 200 mg, serum estrogen levels increase dramatically. However, larger individual doses (e.g., 300 mg) are required to increase serum testosterone levels.

For example, King and colleagues studied the effects of a single 100-mg oral dose of androstenedione in 10 men between the ages of 19 and 29 and reported that although serum androstenedione and estradiol levels increased significantly, testosterone levels did not change (13). These investigators then specifically measured the portion of circulating testosterone that is not bound to protein and considered the "bioactive" portion (called "free testosterone") and similarly saw no effect of the supplement. In a separate study, Leder and colleagues gave 0, 100, or 300 mg of androstenedione to normal healthy men between the ages of 20 and 40 for seven days and took frequent blood samples on days 1 and 7 (14). As in the study by King, they also found that men receiving both the 100- and 300-mg doses of androstenedione experienced dramatic increases in serum estradiol that were often well above the normal male range. Another similarity was that 100-mg dose

Figure 3 Percentage change in serum testosterone and estradiol in healthy men after a single androstenedione dose (as measured by eight hours of frequent blood sampling). Source: Adapted from Ref. 14.

did not affect serum testosterone levels. As shown in Figure 3, however, the novel finding of this study was that 300 mg of androstenedione increased serum testosterone levels significantly, even though by only a modest amount (34%).

Leder and colleagues further observed that there was a significant degree of variability among men with regard to their serum testosterone response after androstenedione ingestion. As shown in Figure 4, some subjects, even in the 300-mg dose group, experienced relatively little change in testosterone levels, whereas serum testosterone levels doubled in other men. This finding suggests that there may be individual differences in the way androstenedione is metabolized that could impact any one person's physiological response to taking the supplement.

Brown and colleagues investigated the hormonal response in a group of men between the ages of 30 and

Figure 4 Individual variability in the peak serum testosterone level achieved after a single 300-mg dose of androstenedione in men. Each line represents one study subject. Source: Adapted from Ref. 14.

56 (10). In this study, subjects consuming 100 mg of androstenedione three times daily experienced increases in serum estrogens but not in serum testosterone. However, unlike in the study by King and colleagues discussed in the previous text, free testosterone did increase significantly (even though again by only a small amount).

Finally, several studies have compared the hormonal effects of androstenedione with those of other "prohormone" dietary supplements. Broeder and colleagues studied the results of a 100-mg twice-daily dose of oral androstenedione, androstenediol (a closely related steroid hormone), or placebo in men between the ages of 35 and 65 (7). They found that both compounds increased estrogen levels but neither affected total serum testosterone levels. Similarly, Wallace and colleagues studied the effects of 50-mg twice-daily doses of androstenedione and DHEA in normal men and reported no increases in serum testosterone levels with either (16).

EFFECTS ON MUSCLE SIZE AND STRENGTH IN MEN

The results of the studies discussed earlier suggest that androstenedione use in men would be less likely to promote the muscle building and performance-enhancing effects associated with testosterone use and more likely to induce the undesirable feminizing effects associated with estrogens. Several studies have assessed the ability of androstenedione (with or without exercise) to increase muscle size and strength and have been uniformly disappointing (7,9,13,15,16). For example, Broeder and colleagues, in the study described earlier, also measured changes in body composition and strength in subjects taking 100 mg androstenedione twice daily in combination with a 12-week intensive weight-training program (7). Despite using sensitive methods that can detect small changes in body composition, they found no differences in muscle mass, fat mass, or strength in the subjects receiving androstenedione compared with those receiving a placebo tablet. Importantly, however, in this study as well as all of these studies referenced earlier, the supplement was given in doses that were not sufficient to increase testosterone levels. It thus remains unknown whether doses of androstenedione sufficient to increase testosterone levels enhance muscle mass or athletic performance.

METABOLISM OF ANDROSTENEDIONE IN MEN

One of the consistent findings of the various androstenedione studies in men is the inefficiency of conversion of the supplements to testosterone. Leder and colleagues explored this issue further by investigating the pattern of androstenedione metabolism in healthy men (17). Specifically, they measured the concentration of inactive testosterone metabolites (also called "conjugates") in the urine of subjects ingesting androstenedione and found an increase of over 10-fold compared with their baseline levels. This finding was in direct contrast to the much more modest changes in serum testosterone they had observed. It suggests that although much of the androstenedione

Figure 5 Serum testosterone levels during 12 hours of frequent blood sampling in postmenopausal women. Circles represent control subjects receiving no supplement, triangles those receiving 50 mg of androstenedione, and squares those receiving 100 mg. Source: Adapted from Ref. 18.

that is absorbed after oral administration is converted to testosterone, it is then immediately further metabolized to inactive compounds in the liver. The investigators confirmed this hypothesis by directly measuring the concentration of one of these inactive metabolites (testosterone glucuronide) in the serum of these subjects. As expected, they found that testosterone glucuronide levels increased by 500% to 1000% (as opposed to the 34% increase in biologically active serum testosterone after a single 300-mg dose of oral androstenedione). Together, these findings demonstrate the effectiveness of the liver in inactivating steroid molecules when taken orally.

PHARMACOKINETICS AND HORMONAL EFFECTS OF ANDROSTENEDIONE IN WOMEN

Since the initial report of androstenedione administration in two women in 1962 (6), research into the effects of the supplement has focused largely on the hormonal response to oral administration in young men. Between 2002 and 2003, however, two studies on women were published. The first of these studies examined the effects of a single dose of 0, 50, or 100 mg of androstenedione in postmenopausal women (18). The findings of this study were surprising. In contrast to the effects observed in men, even these low doses increased testosterone levels significantly in women (Fig. 5).

Also, unlike the results seen in men, estradiol levels were unaffected by androstenedione administration. In the other study, 100 mg of androstenedione was administered to young, premenopausal, healthy women. Similar to postmenopausal women, these subjects experienced significant increases in serum testosterone levels after androstenedione administration (estradiol was not measured) (19). Importantly, in both of these studies, the peak testosterone levels achieved by the older and younger women taking androstenedione were often significantly above the normal range. Together, these results predict that the physiological effects of the supplement may be different in men and women, as might their potential toxicities. To date, however, there have been no

published reports investigating the long-term physiological effects in women.

ADVERSE EFFECTS AND TOXICITY

Ever since the publicity surrounding androstenedione exploded in 1999, many reports in the lay press have focused on the potential dangerous side effects. Nonetheless, with the exception of a single case description of a man who developed two episodes of priapism in the setting of androstenedione ingestion (20), there have been no published reports of androstenedione-associated serious adverse events. This fact should be only partially reassuring, however, because androstenedione's prior classification as a dietary supplement (as opposed to a drug) allowed manufacturers to avoid responsibility for rigorously monitoring any potential toxicity of their product.

It is well known that oral administration of certain testosterone derivatives can cause severe liver diseases, and anabolic steroid use in general is associated with anecdotal reports of myocardial infarction, sudden cardiac death, and psychiatric disturbances ("roid rage"). Nonetheless, despite androstenedione's close chemical similarity to these substances, it is important to note that it is not a potent anabolic steroid nor does it have a chemical structure similar to those specific compounds that cause liver problems. Thus, the potential of androstenedione to cause these particular serious side effects appears to be limited. Of more pressing concern to clinicians are the possible long-term effects in specific populations. In clinical trials, the supplement was generally well tolerated, though several studies did report that it reduces high-density lipoprotein (or "good cholesterol") levels in men. Importantly, however, even the longest of these studies lasted only several months. It thus remains quite possible that androstenedione use, especially at high doses, could cause subtle physiological changes over prolonged periods that could directly lead to adverse health consequences. In men, for example, the dramatic increase in estradiol levels observed with androstenedione administration could, over time, lead to gynecomastia (male breast enlargement), infertility, and other signs of feminization. In women, because the supplement increases testosterone levels above the normal range, it could cause hirsutism (excess body hair growth), menstrual irregularities, or male-like changes in the external genitalia. In children, increases in both testosterone and estrogen levels could cause precocious puberty or premature closure of growth plates in bone, thereby compromising final adult height.

PURITY OF COMMERCIALLY AVAILABLE ANDROSTENEDIONE

During its period of over-the-counter availability, androstenedione was available from multiple manufacturers and could be purchased as a tablet, capsule, sublingual tablet, or even a nasal spray. Often, it was combined with other products that claimed to limit its potential side effects (such as chrysin, for example, which is purported to decrease androstenedione's conversion to estrogens). Because the manufacture of dietary supplements was not

Table 1 Analysis of Nine Common Brands of Androstenedione Supplements

subject to the same regulations as pharmaceuticals, the purity and labeling of androstenedione-containing products were often inaccurate. Catlin and colleagues, for example, reported that urine samples from men treated with androstenedione contained 19-norandrosterone, a substance not associated with androstenedione metabolism but rather with the use of a specific banned anabolic steroid (21). Further investigation revealed that the androstenedione product used contained a tiny amount of the unlabeled steroid "19-norandrostenedione." Though the amount of 19-norandrostenedione was not physiologically significant, it was enough to cause a "positive" urine test for illegal anabolic steroid use when tested in the standard fashion. In fact, it is precisely this type of contamination that may have explained increases in positive tests for 19-norandrosterone among competitive athletes in the past decade. Additionally, it is now common for athletes who test positive for norandrosterone or other androgenic metabolites to point to dietary supplement contamination as the potential explanation.

Catlin and colleagues also analyzed nine common brands of androstenedione and showed that there was considerable variation and mislabeling among products in terms of both purity and content (Table 1).

REGULATORY STATUS AND DETECTION

Androstenedione was available over-the-counter from 1994 (when the DSHEA was passed) until it was reclassified as an anabolic steroid by the Anabolic Steroid Control Act in 2004. It is important to note that this reclassification came without any evidence that androstenedione increased muscle mass or strength, which was the previous legal definition of an anabolic steroid. Virtually all sports organizations, including the National Football League, the National Collegiate Athletic Association, and the International Olympic Committee, have banned androstenedione. Despite these prohibitions, detection of androstenedione has not been standardized. Specifically, the method used most often to detect testosterone use, measurement of the urinary testosterone-to-epitestosterone ratio, has not proven to be reliable in establishing androstenedione use (22). Further study is still needed to define novel testing procedures that are able to detect androstenedione use reliably.

CONCLUSIONS

Androstenedione is a steroid hormone, which, until 2004, was a popular over-the-counter dietary supplement. Since then, however, it has been classified as an anabolic steroid, and hence a controlled substance. It is purported to increase strength, athletic performance, libido, sexual performance, energy, and general quality of life. Studies indicate that when taken orally by men, small doses are converted to potent estrogens and larger doses to both testosterone and estrogens. Comparatively, there appears to be a much more physiologically important increase in estrogens compared with testosterone in men. In women, the effects are reversed. Studies have thus far failed to confirm any effect on muscle size or strength, though the dosing regimens were modest. Although documentation of adverse side effects among users of androstenedione is scarce, there is considerable concern over potential long-term toxicity, especially in women and adolescents.

L-Arginine

Mauro Maccario, Guglielmo Beccuti, Valentina Gasco, Mariangela Seardo, Gianluca Aimaretti, Emanuela Arvat, Fabio Lanfranco, and Ezio Ghigo

INTRODUCTION

Arginine was first isolated in 1895 from animal horn. It is considered a nonessential amino acid under physiological conditions; however, it may be classified as semi-essential (or conditioned) in newborns, young children, or other circumstances characterized by accelerated tissue growth (e.g., infection, sepsis, trauma) when its production may be too slow and not sufficient to meet the requirements (1). Arginine is physiologically active in the L-form (L-Arg) and participates in protein synthesis in cells and tissues. It is essential for the synthesis of urea, creatine, creatinine, and pyrimidine bases. It also strongly influences hormonal release and has an important role in vasculature dynamics, participating in the synthesis of nitric oxide (NO).

BIOCHEMISTRY

Dietary arginine is particularly abundant in wheat germ and flour, buckwheat, oatmeal, dairy products (cottage cheese, ricotta cheese, nonfat dry milk, skimmed yogurt), chocolate, beef (roasts, steaks), pork, nuts (coconut, pecans, walnuts, almonds, hazel nuts, peanuts), seeds (pumpkin, sesame, sunflower), poultry (chicken, turkey), wild game (pheasant, quail), seafood (halibut, lobster, salmon, shrimp, snails, tuna), chick peas, and soybeans (2).

L-Arg, delivered via the gastrointestinal tract, is absorbed in the jejunum and ileum of the small intestine. A specific amino acid transport system facilitates this process and participates also in the transport of the other basic amino acids, L-lysine and L-histidine. About 60% of the absorbed L-Arg is metabolized by the gastrointestinal enterocytes, and only 40% remains intact reaching the systemic circulation.

An insufficient arginine intake produces symptoms of muscle weakness, similar to muscular dystrophy (3). Arginine deficiency impairs insulin secretion, glucose production, and liver lipid metabolism (4). Conditional deficiencies of arginine or ornithine are associated with the presence of excessive ammonia in the blood, excessive lysine, rapid growth, pregnancy, trauma, or protein deficiency and malnutrition. Arginine deficiency is also associated with rash, hair loss and hair breakage, poor wound healing, constipation, fatty liver, hepatic cirrhosis, and hepatic coma (4).

Depending on nutritional status and developmental stage, normal plasma arginine concentrations in humans and animals range from 95 to 250 $\mu\text{mol/L}$. Toxicity and

symptoms of high intake are rare, but symptoms of massive dosages may include thickening and coarsening of the skin, muscle weakness, diarrhea, and nausea.

The proximal renal tubule accounts for much of the endogenous production of L-Arg from L-citrulline. In the tubule, arginine reacts via the Krebs cycle with the toxic ammonia formed from nitrogen metabolism, producing the nontoxic and readily excretable urea (Fig. 1) (5). If this mechanism does not efficiently handle metabolic byproducts and if L-Arg intake is insufficient, ammonia rapidly accumulates, resulting in hyperammonemia.

L-Arg undergoes different metabolic fates. NO, L-citrulline, L-ornithine, L-proline, L-glutamate, and polyamine-like putrescine are formed from L-Arg. Moreover, the high-energy compound NO-creatinine phosphate, which is essential for sustained skeletal muscle contraction, is also formed from L-Arg (Fig. 2).

L-Arg, its precursors, and its metabolites are deeply involved in the interaction of different metabolic pathways and interorgan signaling. The amino acid influences the internal environment in different ways: disposal of protein metabolic waste; muscle metabolism; vascular regulation; immune system function; healing and repair of tissue; formation of collagen; and building of new bone and tendons.

A leading role for arginine has been shown in the endocrine system, vasculature, and immune response.

PHYSIOLOGY

Endocrine Actions

L-Arg functions as a secretagogue of a number of important hormones at the pituitary, pancreas, and adrenal levels. The effects on growth hormone (GH), prolactin (PRL), adrenocorticotrophic hormone (ACTH), and insulin secretion will be discussed in detail.

GH Secretion

Among the various factors modulating somatotropin function, arginine is well known to play a primary stimulatory influence. Arginine has been shown to increase basal GH levels and to enhance the GH responsiveness to growth hormone releasing hormone (GHRH) both in animals and in humans throughout their life span (6-9); its GH-stimulating activity occurs after both IV and oral administration and is dose dependent; 0.1 and 0.5 g/kg are the minimal and the maximal IV effective doses, respectively. Moreover, a low orally administered arginine dose has been shown to be as effective as a high IV dose in enhancing the GH response to GHRH both in children and in elderly subjects (10,11).

Arginine, directly or indirectly via NO, is likely to act by inhibiting hypothalamic somatostatin (SS) release. It has been shown that arginine—but not isosorbide-dinitrate and molsidomine, two NO donors—stimulates GH secretion (12,13), suggesting that it does not exert its effects through the generation of NO. Moreover, arginine does not modify either basal or GHRH-induced GH increase from rat anterior pituitary (14). On the contrary, it potentiates the GH response to the maximal GHRH dose in humans. Arginine can elicit a response even when the response has been previously inhibited by a GHRH ad-

ministration, which induces an SS-mediated negative GH autofeedback (7,8,15). Moreover, arginine counteracts the GH-inhibiting effect of neuroactive substances that act by stimulating SS release; it does not modify the GH-releasing activity of stimuli acting via SS reduction (8). Again, in favor of an SS-mediated mechanism is also the evidence that ornithine, the active form of arginine, is unable to modify plasma GHRH levels in humans (16). Moreover, arginine fails to potentiate the increased spontaneous nocturnal GH secretion, which is assumed to reflect circadian SS hyposecretion and GHRH hypersecretion, respectively (8). Arginine does not influence the strong GH-releasing action of ghrelin, the natural ligand of GH secretagogue receptors, which is supposed to act as a functional antagonist of SS at both the pituitary and the hypothalamic levels (17,18).

The GH-releasing activity of arginine is sex dependent but not age dependent, being higher in females than in males but similar in children, young, and elderly subjects (8,19–23). Moreover, it has been clearly demonstrated that arginine totally restores the low somatotrope responsiveness to GHRH in aging, when a somatostatinergic hyperactivity is likely to occur (20–23). This evidence clearly indicates that the maximal secretory capacity of somatotrophic cells does not vary with age and that the age-related decrease in GH secretion is due to a hypothalamic impairment (20–23). This also points out the possible clinical usefulness of this substance to rejuvenate the GH/insulin-like growth factor-I (IGF-I) axis in aging. In fact, the reduced function of the GH/IGF-I axis in aging may account for the changes in body composition, structure, and function. In agreement with this assumption, it has been reported by some, but not all, authors that elderly subjects could benefit from treatment with rhGH to restore IGF-I levels within the young range (21,24). As it has been demonstrated that the GH releasable pool in the aged pituitary is basically preserved and that the age-related decline in GH secretion mostly reflects hypothalamic dysfunction (21,23), the most appropriate, that is, “physiological,” approach to restore somatotroph function in aging would be a treatment with neuroactive substances endowed with GH-releasing action. Among these GH secretagogues, arginine received considerable attention. In fact, the coadministration of arginine (even at low oral doses) with GHRH (up to 15 days) enhanced the GH responsiveness to the neurohormone in normal aged subjects (11). However, the efficacy of long-term treatment with oral arginine to restore the function of the GH/IGF-I axis in aging has never been shown in elderly subjects.

Following the evidence that GHRH combined with arginine becomes the most potent and reproducible stimulus to diagnose GH deficiency throughout the life span (25), GHRH + arginine is, at present, one of the two gold standard tests for the diagnosis of GH deficiency (25,26). In fact, the GH response to a GHRH + arginine test is approximately threefold higher than the response to classical tests and does not vary significantly with age (25,26). Because of its good tolerability and its preserved effect in aging, the GHRH + arginine test is currently considered to be the best alternative choice to the insulin-induced tolerance test (ITT) for the diagnosis of GH deficiency throughout the life span (25).

PRL Secretion

Among the endocrine actions of arginine, its PRL-releasing effect has been shown both in animals and in humans after IV but not after oral administration (10,27). The PRL response to arginine is markedly lower than the response to the classical PRL secretagogues, such as dopaminergic antagonists or thyrotropin-releasing hormone (TRH) (6) but higher than that observed after secretion of GH and other modulators of lactotrope function (17).

The mechanisms underlying the stimulatory effect of arginine on PRL secretion are largely unknown, but there is evidence that this effect is not mediated by galanin, a neuropeptide with PRL-releasing effect. In fact, galanin has been shown to potentiate PRL response to arginine, suggesting different mechanisms of action for the two substances (28).

ACTH Secretion

Although some excitatory amino acids and their agonists have been demonstrated to differently modulate corticotropin-releasing hormone and arginine vasopressin release in vitro and influence both sympathoadrenal and hypothalamo-pituitary-adrenal (HPA) responses to hypoglycemia in animals (29,30), little is known about arginine influences on HPA axis in humans. Many studies have shown that mainly food ingestion influences spontaneous and stimulated ACTH/cortisol secretion in normal subjects and that central α_1 -adrenergic-mediated mechanisms are probably involved (31). In humans free fatty acids inhibit spontaneous ACTH and cortisol secretion, but no data exist regarding the effect of each nutrient component on HPA function. Previous studies demonstrated that arginine is unable to exert an ACTH-stimulatory effect in humans via generation of NO (12) and our unpublished preliminary data failed to demonstrate a significant effect of arginine (30 g IV) on either ACTH or cortisol secretion in normal subjects.

Insulin Secretion

Arginine is one of the most effective known insulin secretagogue and it may be used with glucose potentiation to determine a patient's capacity to secrete insulin (32). Arginine acts synergistically with glucose, and to a much lesser extent with serum fatty acids, in stimulating insulin release. A synergistic effect of arginine and glucose on insulin secretion has been shown in humans (33,34), and the combined administration of these two stimuli has been studied in an attempt to test β -cell secretory capacity in diabetic patients (35).

A protein meal leads to a rapid increase in both plasma insulin and glucagon levels (36). Administration of arginine has a similar effect. An arginine transport system is present in the β -cell plasma membrane (37). When arginine enters the β cell, it causes ionic changes that depolarize the β cell and trigger Ca^{2+} uptake and exocytosis of insulin-containing granules.

Several mechanisms for arginine-induced β -cell stimulation have been proposed. These include the metabolism of L-Arg leading to the formation of ATP (38,39), the generation of NO (40,41), and the direct depolarization of the plasma membrane potential due to the accumulation of the cationic amino acid (42–44).

A sustained Ca^{2+} influx is directly related to insulin secretion following arginine uptake by β cells. The arginine-induced increase in Ca^{2+} concentration is inhibited by the activation of ATP-sensitive potassium (K-ATP) channels with diazoxide and seems dependent on the nutritional status. These observations suggest that the K-ATP channels, when fully open, act to prevent membrane depolarization caused by arginine. The presence of a nutrient, such as glucose, produces sufficient closure of K-ATP channels to allow arginine-induced membrane depolarization and activation of the voltage-activated Ca^{2+} channels (37).

Nonendocrine Actions

Cardiovascular System

Increasing interest has been recently focused on NO. This mediator, which is synthesized from L-Arg (45) by nitric oxide synthases (NOS) (46), is a potent vasodilator (47) and inhibitor of platelet adhesion and aggregation (48). Three isoforms of NOS are described: neuronal NOS (nNOS—NOS-1), inducible NOS (iNOS—NOS-2), and endothelial NOS (eNOS—NOS-3). NOS-1 and NOS-3 are expressed constitutively and they produce NO at low rates (49). NOS-3 is responsible for a consistent vasodilator tone and, although constitutive, can be regulated by endothelial shear stress (50) and substances such as acetylcholine, histamine, serotonin, thrombin, bradykinin, and catecholamines. Calcium is required for NOS-3 activation (51). NO production is mainly dependent on the availability of arginine and NOS is responsible for the biochemical conversion of L-Arg to NO and citrulline in the presence of cofactors such as reduced nicotinamide adenine dinucleotide phosphate (NADPH), tetrahydrobiopterin (BH_4), flavin mononucleotide, and flavin adenine nucleotide. Reduced NO production, leading to vasoconstriction and increases in adhesion molecule expression, platelet adhesion and aggregation, and smooth muscle cell proliferation has been demonstrated in atherosclerosis, diabetes mellitus, and hypertension (52–54)—conditions known to be associated with an increased mortality because of cardiovascular disease. Taken together, these observations lead to the concept that interventions designed to increase NO production by supplemental L-Arg might have a therapeutic value in the treatment and prevention of the endothelial alterations of these diseases. Besides several actions exerted mainly through NO production, arginine also has a number of NO-independent properties, such as the ability to regulate blood and cellular pH, and the effect on the depolarization of endothelial cell membranes.

The daily consumption of arginine is normally about 5 g/day. Arginine supplementation is able to increase NO production, although the K_m for L-Arg is 2.9 μmol and the intracellular concentration of arginine is 0.8 to 2.0 mmol. To explain this biochemical discrepancy, named "arginine paradox," there are theories that include low arginine levels in some diseases (e.g., hypertension, diabetes mellitus, and hypercholesterolemia), and/or the presence of enzymatic inhibitors (55), and/or the activity of the enzyme arginase (which converts arginine to ornithine and urea, leading to low levels of arginine).

Recently attention has been given to the methylated forms of L-Arg, generated by the proteolysis of

methylated proteins; they are represented by asymmetric dimethylarginine (ADMA) and two symmetric dimethylated derivatives: symmetric dimethylarginine (SDMA) and monomethylarginine (MMA) (56). Only ADMA and MMA, but not SDMA, exert inhibitory effects on NOS-3 activity (57). For this reason, ADMA is now recognized as a new emerging cardiovascular risk marker and likely as a causative factor for cardiovascular disease (58).

L-Arginine therapy in cardiovascular pathologies showed contradictory results. However, it is now clear that individual response to L-Arg may be influenced by SDMA. In fact, no effects of L-arg therapy are demonstrated in patients with low ADMA levels, whereas in patients with high ADMA level, L-Arg normalizes the L-Arg to ADMA ratio, thus normalizing the endothelial function (59).

Several studies demonstrated that L-Arg infusion in normal subjects and patients with coronary heart disease (60), hypercholesterolemia (61), and hypertension (62) is able to improve the endothelial function, but the results, although encouraging, are not conclusive because of the short-term effects of IV arginine. However, arginine does not affect endothelial function in patients with diabetes mellitus. On the other hand, oral L-Arg has a longer half-life and longer-term effects than L-Arg given intra-arterially or intravenously (63). Thus, in the setting of long-term health maintenance or symptom management, the oral route would be preferred. Studies in animals documented that oral L-Arg supplementation is able to reduce the progression of atherosclerosis, preserving endothelium function (64) and inhibiting circulating inflammatory cells (65) and platelets (66) in animals with hypercholesterolemia, and to decrease blood pressure and wall thickness in animals with experimental hypertension (67). On the other hand, studies in humans *in vivo* are not so widely positive as the animal experimental data. Actually, although the majority of the data is in normal subjects, individuals with a history of cigarette smoking and patients with hypercholesterolemia and claudication demonstrate beneficial effects of oral L-Arg administration on platelet adhesion and aggregation, monocyte adhesion, and endothelium-dependent vasodilation (68,69). Other studies do not show any benefit (70,71); therefore, no definitive conclusions can be drawn. Taken together, the studies show a major effect when L-Arg supplementation was given in subjects with hypercholesterolemia, probably because of an increase in NO production via reduction of the ADMA intracellular concentration, which is increased in the presence of LDL hypercholesterolemia.

In conclusion, despite several beneficial effects on intermediate end points, particularly in hypercholesterolemic patients, there is no evidence for a clinical benefit in the treatment or prevention of cardiovascular disease. More data, derived from large-scale prospective studies evaluating the effect of long-term treatment with L-Arg, are needed. Future perspectives of pharmacological intervention are represented by the regulation of the enzyme dimethylarginine dimethylaminohydrolase responsible for the ADMA metabolism (57), the arginase (72), and the endothelial cell L-Arg transporter (73).

Immune System

Many studies, in animals as well as in humans, have shown that arginine is involved in immune modulation. In

fact, this amino acid is a component of most proteins and the substrate for several nonprotein, nitrogen-containing compounds acting as immune modulators.

There is clear evidence that arginine participates in the cell-mediated immune responses of macrophages and T lymphocytes in humans through the production of NO by inducible nitric oxide synthase (iNOS—NOS-2), which occurs mostly in the macrophage (74,75), and through the modulation of T-lymphocyte function and proliferation (76,77). At intracellular levels, arginine is metabolized by two different enzymatic pathways: the arginase pathway, by which the guanidino nitrogen is converted into urea to produce ornithine, and the NOS pathway, which results in oxidation of the guanidino nitrogen to produce NO and other substances (78,79).

It has been shown that macrophage superoxide production, phagocytosis, protein synthesis, and tumoricidal activity are inhibited by high levels of arginine *in vitro* and that sites of inflammation with prominent macrophage infiltration, such as wounds and certain tumors, are deficient in free arginine (80). In particular, a decrease in arginine availability due to the activity of macrophage-derived arginase rather than the arginine/NO pathway may contribute to the activation of macrophages migrating at inflammatory sites (80). Arginine metabolism in the macrophages is activity dependent. At rest, macrophages exhibit minimal utilization of arginine and lower NOS-2 expression or arginase activity, whereas in activated cells, arginine is transported into the cell, and NOS-2 expression and arginase are induced by cytokines and other stimuli (81). The types of stimuli that induce NOS-2 and arginase are quite different. *In vitro* and *in vivo* studies demonstrated that NOS-2 is induced by T-helper I cytokines (IL-1, TNF, and γ -interferon) produced during activation of the cellular immune response, such as severe infections or sepsis (74,75), whereas arginases are induced by T-helper II cytokines (IL-4, IL-10, and IL-13) and other immune regulators aimed at inducing the humoral immune response (82,83). Thus, in disease processes, where inflammatory response predominates, NOS-2 expression and NO production prevail. Under biological circumstances where T-helper II cytokine expression is prevalent, arginase activity and the production of ornithine and related metabolites would predominate.

In vitro studies in animals demonstrated depressed lymphocyte proliferation in cultures containing low levels of arginine and maximal proliferation when arginine is added at physiological plasma concentration (77,84), but the molecular details have not been completely defined.

It has also been shown that supplemental arginine increased thymic weight in rodents because of increased numbers of total thymic T lymphocytes. On the other hand, in athymic mice, supplemental arginine increased the number of T cells and augmented delayed-type hypersensitivity responses, indicating that it can exert its effects on peripheral lymphocytes and not just on those within the thymus (76).

The immunostimulatory effects of arginine in animal studies have suggested that this amino acid could be an effective therapy for many pathophysiological conditions in humans, able to positively influence the immune response under some circumstances by restoring cytokine balance and reducing the incidence of infection.

In healthy humans, oral arginine supplementation shows many effects on the immune system, including increase in peripheral blood lymphocyte mitogenesis, increase in the T-helper-T-cytotoxic cell ratio and, in macrophages, activity against microorganisms and tumor cells (85). Furthermore, the delayed-type hypersensitivity response as well as the number of circulating natural killer (NK) and lymphokine-activated killer cells are increased (85–87). Therefore, it has been hypothesized that arginine could be of benefit to patients undergoing major surgery after trauma and sepsis and in cardiovascular diseases, HIV infection, and cancer (88). In fact, short-term arginine supplementation has been shown to maintain the immune function during chemotherapy; arginine supplementation (30 g/day for 3 days) reduced chemotherapy-induced suppression of NK cell activity, lymphokine-activated killer cell cytotoxicity, and lymphocyte mitogenic reactivity in patients with locally advanced breast cancer (89). It must be noted that chronic administration of arginine has also been shown to promote cancer growth by stimulating polyamine synthesis in both animal and human studies (89). On the other hand, NO has been shown to inhibit tumor growth. Thus, the real effect on cancer processes depends on the relative activities of NOS and arginase pathways that show variable expression, depending on the stage of carcinogenesis (91).

These data clearly indicate the involvement of arginine in immune responses in both animals and humans. Large clinical trials are needed to clarify the clinical application and efficacy of this amino acid in immunity and immunopathology.

SUPPLEMENTAL ARGININE

The available form of supplemental L-Arg is represented by the free base, the Cl⁻ salt (L-Arg hydrochloride—L-Arg-HCl) and the aspartate salt of the amino acid (92).

L-Arg is stable under sterilization condition and its administration is safe for mammals in an appropriate dose and chemical form (91).

Oral L-Arg (up to 9 g of Arg-HCl per day for adults) has no adverse effects on humans but higher doses can lead to gastrointestinal toxicity, theoretically increasing local production of NO and impairing intestinal absorption of other basic amino acids (91). Moreover, the local NO production may be particularly dangerous if intestinal diseases are present (92).

Oral L-Arg supplement is commonly used to increase GH release and consequentially physical performance; moreover, it has been hypothesized that L-Arg supplement could lead to improved muscular aerobic metabolism and less lactate accumulation, enhancing NO-mediated muscle perfusion.

However, in a clinical trial, arginine supplement in endurance-trained athletes did not show any difference from placebo in endurance performance (maximal oxygen consumption, time to exhaustion), endocrine (GH, glucagon, cortisol, and testosterone concentrations), and metabolic parameters (93).

In another study, the association “arginine plus exercise” produced a GH response approximately 50% lower than that observed with exercise alone, suggesting that

the acute use of oral L-Arg prior to exercise blunts the GH response to subsequent exercise (94).

No effects on NO production, lactate and ammonia metabolism, and physical performance in intermittent anaerobic exercise were shown in well-trained male athletes after short-term arginine supplementation (95). It has been hypothesized that NO production is not modified by arginine supplementation in athletes because they may have higher basal concentrations of NO than general population; in fact, basal NO production can be increased by regular exercise training, without any pharmacological intervention (95).

There are many interesting clinical perspectives on arginine supplementation therapy, especially in critical care setting (96), treatment and prevention of pressure ulcers (97), hypertension (59), and asthma and chronic obstructive pulmonary disease (98), but further studies are required to clarify which categories of patients may benefit from this treatment (99).

CONCLUSIONS

From an endocrinological point of view, the simple classification of arginine as an amino acid involved in peripheral metabolism is no longer acceptable. In fact, besides other nonendocrine actions, it has been clearly demonstrated that arginine plays a major role in the neural control of anterior pituitary function, particularly in the regulation of somatotrophin secretion. One of the most important concepts regarding arginine is the existence of an arginine pathway at the CNS level, where this amino acid represents the precursor of NO, a gaseous neurotransmitter of major importance. On the other hand, NO does not necessarily mediate all the neuroendocrine or the peripheral arginine actions.

In the past years, new discoveries have led to a rapid increase in our knowledge of the arginine/NO system, from a neuroendocrine and nonendocrine point of view. Up to now, there is no evidence for the utility of L-Arg supplement for muscle strength or exercise performance in humans. However, several other aspects still remain to be clarified; the potential clinical implications for arginine have also never been appropriately addressed and could provide unexpected results both in the endocrine and in the cardiovascular fields.

Astragalus

Roy Upton

INTRODUCTION

Astragalus root (*Astragalus membranaceus* and *Astragalus mongholicus*) (Figs. 1 and 2; flowers are shown in Fig. 2) is one of the most important plant products used in traditional Chinese medicine (TCM) for supporting immune resistance (衛氣; wei qi) and energy production (補氣; bu qi). Astragalus is also one of the most popular ingredients in botanical dietary supplements for its putative effect of supporting healthy immune function. Despite the widespread use of this botanical among TCM practitioners and its extensive use in botanical supplements, there are few clinical trials supporting its use, though those that are available are positive. Numerous preclinical studies provide evidence for a number of pharmacological effects that are consistent with the traditional and modern use of astragalus.

BACKGROUND

Traditional and Modern Uses

In Asia, astragalus is commonly used according to both its traditional Chinese medical indications as a general tonifier and specifically for immune enhancement and for modern biomedical indications such as immune, liver, and cardiovascular support. It has been used for the prevention of the common cold and upper respiratory tract infections and is widely prescribed to children for prevention of infectious disease, though formal clinical English language studies regarding this use are lacking. In the West, astragalus is primarily used as an immune modulator. Astragalus potentiates recombinant interleukin-2 (rIL-2) and recombinant interferon-1 and -2 (rIFN-1 and -2) immunotherapy and by lowering the therapeutic thresholds, may reduce the side effects normally associated with these therapies. The data and opinion of those expert with the use of the botanical suggest that astragalus is useful as a complementary treatment during chemotherapy and radiation therapy and in immune deficiency syndromes. There is some modern evidence for its use in hepatitis and the treatment of cardiovascular disease.

In TCM and Western clinical herbal medicine, astragalus is most commonly used in combination with other botanicals and is very seldom used as a single agent. There are numerous studies of some of the classic combinations of astragalus (e.g., astragalus and *Angelica sinensis*). These have not been reviewed, but use of formulas is more consistent with the use of the astragalus than with the use of the herb alone according to traditional Chinese medical principles.

CHEMISTRY AND PREPARATION OF PRODUCTS

The primary compounds of interest in astragalus are triterpenes, polysaccharides, and flavonoids. The triterpene astragaloside IV is a relatively unique marker for astragalus species used in Chinese medicine. A variety of preparations are utilized in clinical practice and in herbal supplements. A number of preparations, including crude extracts, isolated polysaccharides, and triterpene saponins, have been subject to study and correlated with activity. Clinically, in China and among some practitioners in the United States, decoctions are frequently given. However, due to the time required for cooking and the subsequent smell and taste of Chinese herb preparations in general (though astragalus is very agreeable), many consumers and practitioners prefer crude powder or extract preparations (capsules, tablets), freeze-dried granules, or liquid extracts. Astragalus is also used as a relatively common ingredient in soups, especially during winter months.

Polysaccharides (12–36 kD) have been most often correlated with immune activity, while triterpene saponins have been predominantly associated with cardiovascular and hepatoprotective effects. Astragalus polysaccharides are generally composed of a mixture of D-glucose, D-galactose, and L-arabinose or D-glucose alone. The glucose units appear to be primarily α -(1,4)-linked with periodic α -(1,6)-linked branches (1,2). The triterpene glycosides vary by position, number, and type of sugar residues at positions 3, 6, and 25. Several of these “astragalosides” (e.g., astragaloside IV; Fig. 3) are composed of a single xylopyranosyl substituent at the 3-position, which may or may not be acetylated. Others possess either disaccharide or trisaccharide substituents (3–5). Primary flavonoids of astragalus for which activity has been reported include calycosin, formononetin (Fig. 3), and daidzein (Fig. 3) and additionally include isorhamnetin, kaempferol, and quercetin, among others (6).

PRECLINICAL STUDIES

Pharmacokinetics

Pharmacokinetic data available in English language publications on astragalus, its crude extracts, or its constituents are very limited. In the most detailed study to date, the pharmacokinetics of a decoction of astragalus, the preparation most used traditionally were investigated in four models: four complement in silico, a cacao-2 intestinal cell model, an animal, and a human volunteer ($n = 1$). Intestinal absorption was demonstrated for several flavonoids including calycosin and formononetin, along with their aglycone metabolites in all four

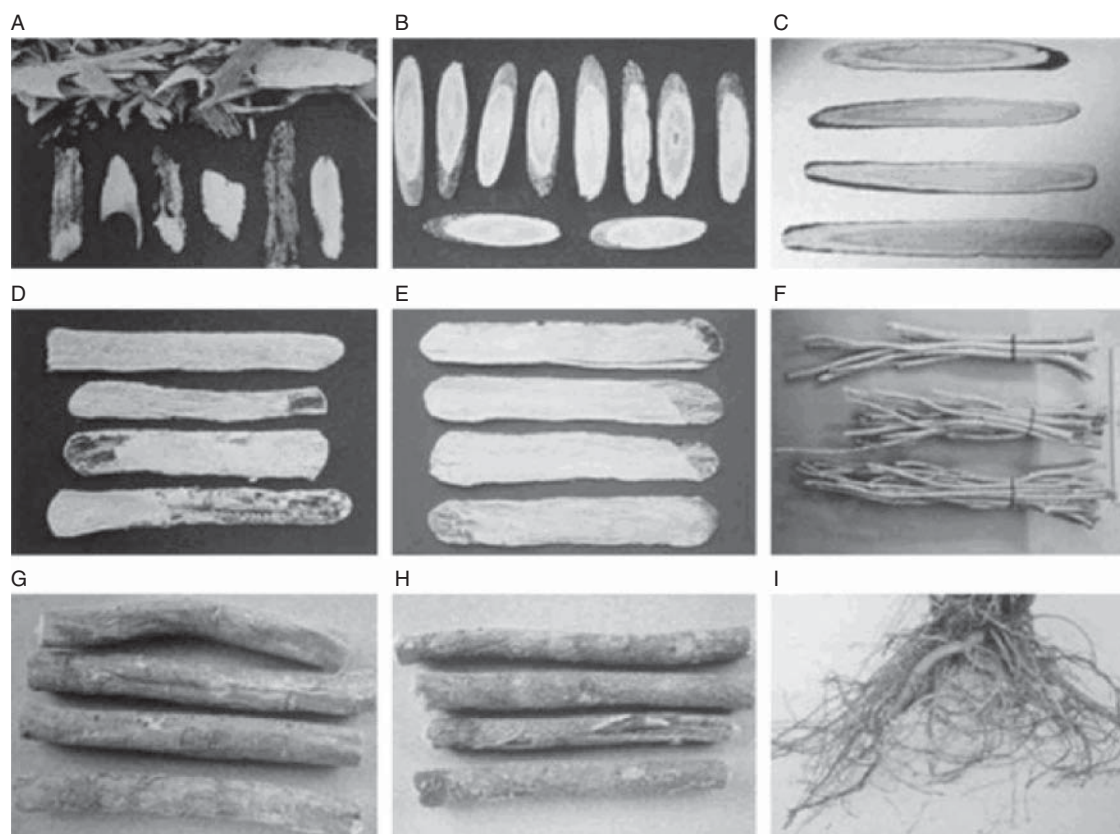

Figure 1 Different forms and quality of astragalus on the American market. Source: Photo courtesy of Roy Upton, Soquel, CA.

models. Triterpene saponins, used as chemical markers of astragalus (e.g., astragaloside I and IV) in the *Pharmacopoeia of the People's Republic of China* and the *American Herbal Pharmacopoeia*, were lacking, likely due to their low concentrations in the preparation. In the human volunteer, nine flavonoids, including calycosin, formononetin, and the isoflavone daidzein, were detected

in urine (7). In animal models (rats and dogs), astragaloside IV, which has demonstrated cardioprotective activity, showed moderate-to-fast elimination. The half-life in male rats was from 67.2 to 98.1 minutes, in female rats 34.0 to 131.6 minutes, and was linear at the intravenous doses given. The highest concentration of astragaloside IV was found in the lungs and liver. Only 50% of the compound was detected in urine and feces. Binding to plasma protein was also linear at the concentration of 250–1000 ng/mL. Slow systemic clearance of astragaloside IV occurred via the liver at approximately 0.004 L/kg/min (8).

In another pharmacokinetic study, a two-compartment, first-order pharmacokinetic model was used to describe the pharmacokinetics of intravenous-administered astragaloside IV. Systemic clearance of this triterpene was reported as moderate and distribution into peripheral tissues was limited (9).

Pharmacodynamics

A large percentage of research on astragalus has focused on its immunostimulatory activity and its purported ability to restore the activity of a suppressed immune system. More recently, interest in its potential as a cardioprotective agent has been shown. Reviews of a limited number of clinical trials and preclinical data provide some evidence for its usefulness in the prevention of the common cold and as an adjunct to cancer therapies. There is limited evidence to suggest a benefit to the cardiovascular

Figure 3 Some major constituents of Astragalus.

system, with improvement in clinical parameters associated with angina, congestive heart failure, and acute myocardial infarct. There is also some indication from animal studies supporting its use in the treatment of hepatitis and diabetes.

Immunomodulatory Effects

There are relatively strong preclinical data of pharmacological mechanisms that provide support for the putative immunomodulatory effects of astragalus.

Cancer

In a rat study, animals were pretreated orally for 50 days with a low or high dose of astragalus extract (3.3 or 10 g/kg/day) prior to IP injection of doxorubicin (cumulative dose of 12 mg/kg over a 2-week period). After 5 weeks of the final injection of doxorubicin, a significant inhibition of cardiac diastolic function was observed. This was accompanied by ascites, catexia, decreased heart weight, and increased mortality. Treatment with astragalus at both doses significantly attenuated the negative effects of doxorubicin on cardiac functions and ascites, while the high dose also improved survival. This protective effective was at least partially associated with the ability of astragalus to attenuate changes in cardiac SERCA2a mRNA expression (10).

A broad array of immunomodulatory effects has been demonstrated in numerous preclinical studies that

suggest a substantial value of astragalus in conjunction with conventional cancer therapies. The most relevant of these was a series of investigations conducted by researchers at the MD Anderson Cancer Center that found that astragalus extract restored to normal the immune response of patients' mononuclear cells that were grafted into rats immunocompromised by cyclophosphamide. These researchers concluded that astragalus and its polysaccharide fraction reversed the immunosuppressive effect of cyclophosphamide (11–15). In other studies, astragalus and its various fractions were shown to stimulate macrophage phagocytosis (16) and hematopoiesis (17).

One study reported on the gastroprotective effects of astragalus extract (characterization not reported) in human peritoneal mesothelial cells (HPMCs) subjected to gastric cancer cell lines. Upon incubation with cancer cell lines, apoptosis of the HPMC cells was observed. The astragalus preparation, via regulation of Bcl-2 and Bax, partially inhibited apoptosis. The authors interpreted these findings as a potential that astragalus may slow down the metastasis of the primary cancer and is therefore a potential treatment for gastric cancer (18).

The ability of an astragalus fraction to potentiate the effects of rIL-2 has been demonstrated in *in vitro* assays. Lymphokine-activated killer (LAK) cells were treated with a combination of the astragalus fraction and 100 units/mL of IL-2. The combination therapy produced the same amount of tumor-cell-killing activity as that generated by 1000 units/mL of rIL-2 on its own, thus suggesting that the astragalus fraction elicited a 10-fold potentiation of rIL-2 in this *in vitro* model (19). These findings were confirmed in a follow-up study by the MD Anderson researchers using LAK cells from cancer and AIDS patients. In this study, the cytotoxicity of a lower dose of 50 μ g/mL of rIL-2 given with the astragalus fraction was comparable to that of a higher dose of 500 μ g/mL of rIL-2 alone against the Hs294t melanoma cell line of LAK cells. With the combination, the effector-target cell ratio could be reduced to one-half to obtain a level of cytotoxicity that was equivalent to the use of rIL-2 alone. In addition, the astragalus fraction was shown to increase the responsiveness of peripheral blood lymphocytes that were not affected by rIL-2. In this study, and in another by the same researchers, it was concluded that the fraction potentiated the activity of LAK cells and allowed for the reduction in rIL-2, thus minimizing the toxicity of rIL-2 therapy (20). Other groups of researchers reported almost identical findings (a 10-fold potentiation) and concluded that astragalus is effective in potentiating IL-2-generated LAK cell cytotoxicity *in vitro* (21,22). Astragalus was also found to enhance the secretion of tumor necrosis factor (TNF) from human peripheral blood mononuclear cells (PBMCs). A polysaccharide fraction (molecular weight 20,000–25,000) increased secretion of TNF- α and TNF- β after isolation of adherent and nonadherent mononuclear cells from PBMCs (23).

Other investigations support the role of astragalus polysaccharides as immunomodulating agents. In an *in vitro* study, astragalus polysaccharides significantly induced the proliferation of BALB/c mouse splenocytes resulting in subsequent induction of interleukin 1 β and tumor necrosis factor- α and the activation of murine macrophages. The researchers concluded

that astragalus had an intermediate-to-high affinity for membrane immunoglobulin (Ig) of β lymphocytes (24).

Cardiovascular Effects

In animal studies, astragalus or its compounds were reported to elicit antioxidant (25), mild hypotensive (26), and both positive (27) (50–200 $\mu\text{g/mL}$) and negative (30 $\mu\text{g/mL}$) inotropic activity (28). The inotropic activity was reported to be due to the modulation of Na^+/K^+ ATPase in a manner similar to strophanthin K. Antioxidant (29), calcium channel blocking (30), and fibrinolytic activity (31) have been reported in in vitro studies. Astragaloside IV was studied for potential cardioactivity. Various effects have been reported. Intravenous administration of astragaloside IV reduced the area of myocardial infarct and reduced plasma creatine phosphokinase release in dogs subjected to 3-hour ligation and increased coronary blood flow in anesthetized dogs. In isolated rat heart perfusion investigations, astragaloside IV significantly improved ($P < 0.01$) postischemic heart function and reduced creatine phosphokinase release from the myocardium. In addition, coronary blood flow during baseline perfusion and reperfusion in ischemic rat hearts was increased, while reperfusion damage was decreased. This activity was shown to be at least partially attributable to coronary dilation via an increase in endothelium-derived nitric oxide. Antioxidant activity via an increase in superoxide dismutase (SOD) activity has also been reported for astragalus and is considered to contribute to its cardioprotective effects (32). Astragaloside IV was also shown to significantly attenuate blood–brain barrier permeability in a rat ischemia/reperfusion model (33).

Hepatoprotective Effects

Hepatoprotective effects against numerous hepatotoxic agents (e.g., acetaminophen, carbon tetrachloride, and *Escherichia coli* endotoxin) have been reported in both animal and in vitro studies. In these experiments, improvement in histological changes in hepatic tissue, including fatty infiltration, vacuolar degeneration, and hepatocellular necrosis, was reported. These effects may be associated with saponin fractions (34). In one clinical study of hepatitis B patients, concomitant use of astragalus with lamivudine and α -2b interferon showed greater efficacy than with lamivudine alone (35).

Systemic Lupus Erythematosus

Astragalus was also studied for its ability to affect natural killer (NK) cell activity, using an enzyme-release assay. The NK cell activity of PBMCs from 28 patients with systemic lupus erythematosus (SLE) was increased after in vitro incubation with an undefined astragalus preparation. Low levels of NK cell activity were correlated with disease activity. PBMCs from patients with SLE had significantly decreased NK cell activity as compared with those from healthy donors. The extent of stimulation by the astragalus preparation was related to the dose and length of the preincubation period (36). Despite its use as an immune-enhancing agent, which would normally be considered contraindicated in autoimmune disorders, investigation of astragalus may be warranted as evidence

suggests that it elicits significant anti-inflammatory activity and improves ratios and function of T lymphocytes in SLE (37).

Viral Infections

Prophylaxis against flu and modulation of endogenously produced interferon have been reported in several animal studies utilizing astragalus alone (6).

Other Effects

In a new line of investigation for astragalus, two triterpenes (astragaloside II and isoastragaloside I) were shown to alleviate insulin resistance and glucose intolerance in mice. The two compounds selectively increased adiponectin secretion on primary adipocytes and potentiated the effects of the insulin-sensitizer rosiglitazone. Chronic administration of the compounds (specific details lacking) to both dietary and genetically obese mice resulted in a significant increase in serum adiponectin, resulting in an alleviation of hyperglycemia, glucose intolerance, and insulin resistance. These effects were diminished in mice lacking adiponectin (38).

One study showed that a liquid extract of astragalus (2 g/mL/intravenous) retarded the progression of renal fibrosis in a manner similar to the angiotensin-II-receptor antagonist losartan. The study reported that like losartan, astragalus decreased deposition of fibronectin and type-I collagen by significantly reducing the expression of transforming growth factor- β_1 and α -smooth muscle actin ($P < 0.05$) (39).

Astragalus was investigated for its potential effect of reducing atopic dermatitis in mice. Using prednisolone (3 mg/kg/day) as a comparator, an astragalus water extract was administered orally at 100 mg/kg. Astragalus significantly reduced the severity of chemically induced inflammation (2,4-dinitrofluorobenzene) to a degree similar to the comparator but, unlike prednisolone, did not inhibit interleukin-4 production (40).

CLINICAL STUDIES

There are both English and Chinese language studies on astragalus. As with much of the literature regarding Chinese herbs, there are few clinical data of high methodological quality. In addition, a positive publication bias regarding Chinese literature has been reported (41), while in primary American medical literature, a negative publication bias against dietary supplement studies has been reported (42).

Immunomodulatory Effects

Cancer

Among modern herbal practitioners, astragalus is recommended as an immune supportive botanical in conjunction with conventional chemo and radiation therapies for cancer. There is a common belief and some clinical and preclinical evidence that astragalus both reduces side effects associated with conventional cancer therapies and can potentiate the effects of certain therapies. The available evidence is not strong enough to recommend astragalus as a standard part of conventional cancer care. However,

its demonstrated safety, lack of negative interaction with conventional therapies, and its putative benefit in building, preserving, and restoring immunocompetency before and after conventional therapies warrant specific study. There is also potential for use of both oral and injectable preparations, the latter of which are not approved in North America but are widely used throughout Asia.

In one clinical study, an astragalus drip (20 mL in 250 mL saline solution daily for 84 days) was administered to cancer patients ($n = 60$). Compared with the control group (no astragalus), those in the astragalus group showed a slower rate of tumor progression, a lower rate of reduction in peripheral leukocytes and platelets, reduction in suppressor CD8s, improved CD4/CD8 ratios, increased IgG and IgM, and better Karnofsky scores (43).

In addition to its use alone, both as a primary treatment and as an adjunct to conventional cancer therapies, astragalus is most often combined with other similar acting immune-enhancing plants. A number of randomized prospective clinical studies of cancer patients were conducted using a combination of astragalus and *ligustrum* (*Ligustrum lucidum*) (undisclosed quantities) with positive results, such as mortality reduction in breast and lung cancer patients (44). These effects, of course, must be considered to be due to the cumulative effects of the two botanicals and cannot be presumed to occur with astragalus alone but are more consistent with the manner in which astragalus is used in TCM.

An early clinical trial reported that 53 cases of chronic leukopenia responded favorably to an astragalus extract (1:1; 2 mL daily intramuscularly for 1–2 weeks). Improvements in symptoms and white blood cell counts were observed, but specific data were lacking (34).

Cardiovascular Effects

Various cardioactive properties have been reported for astragalus, and astragalus is widely used in the treatment of both chronic and acute cardiovascular disease in China. In one study, 92 patients with ischemic heart disease were given an unidentified preparation of astragalus. Marked relief from angina pectoris and other improvements as measured by electrocardiogram (ECG) and impedance cardiogram were reported. Improvement in the ECG index was reported as 82.6%. Overall improvement was significant as compared with the control group ($P < 0.05$) (45). A similar result in cardiac performance was reported by other groups of researchers. In one study, 43 patients were hospitalized within 36 hours of acute myocardial infarct. After administration of an astragalus preparation (undefined profile), the ratio of preejection period/left ventricular ejection time was decreased, the antioxidant activity of SOD of red blood cells was increased, and the lipid peroxidation content of plasma was reduced (46). In another experiment, 20 patients with angina pectoris were given an undefined astragalus preparation. Cardiac output, as measured by Doppler echocardiogram, increased from 5.09 ± 0.21 to 5.95 ± 0.18 L/min 2 weeks after administration of astragalus ($P < 0.01$). In this study, neither improvement in left ventricular diastolic function nor inhibition of adenosine triphosphate was observed (47). Intravenous administration of astragalus (undefined preparation) was reported to significantly shorten the duration of ventric-

ular late potentials in cardiac patients (39.8 ± 3.3 ms vs. 44.5 ± 5.9 ms; $P < 0.01$) (48).

In another investigation, astragaloside IV (intravenous; unspecified amount) was given to patients with congestive heart failure for 2 weeks. Improvement in symptoms such as tightness in the chest, difficult breathing, and reduced exercise capacity were reported. Radionuclide ventriculography showed that left ventricular modeling improved and left ventricular end-diastolic and left ventricular end-systolic volume diminished significantly. The authors concluded that astragaloside IV is an effective positive inotropic agent (49), an action supported by others (27).

Hepatoprotective Effects

In China, astragalus is widely used in the treatment of chronic hepatitis where reductions in elevated liver enzymes and improvements in symptoms in humans have been reported. This activity is stated to be associated with polysaccharides that increase interferon production (35).

Viral Infections

According to one English language review of the Chinese literature, a prophylactic effect against the common cold was reported in an epidemiological study in China involving 1000 subjects. Administration of astragalus, given either orally or as a nasal spray, reportedly decreased the incidence of disease and shortened cold duration. Studies exploring this protective effect found that oral administration of the preparation to subjects for 2 weeks enhanced the induction of interferon by peripheral white blood cells. Levels of IgA and IgG antibodies in nasal secretions were reported to be increased following 2 months of treatment (34). The effect of astragalus on the induction of interferon was studied in a placebo-controlled study involving 28 people. Fourteen volunteers were given an extract equivalent to 8 g of dried root per day and the rest were given placebos. Blood samples were drawn before treatment, then 2 weeks and 2 months after treatment. Interferon production by leukocytes was statistically increased after both time periods ($P < 0.01$) in the astragalus group but not the control group (50). In another study, astragalus was shown to potentiate the effects of interferon (α IFN-1) in patients with chronic cervicitis (51).

Dosages

- Crude root: 9–30 g daily as a decoction (52).
- Decoction: 0.5–1 L daily.

SAFETY PROFILE

Side Effects

None cited in the literature.

Contraindications

None cited in the literature.

Precautions

There is some evidence to suggest that astragalus and its putative anti-inflammatory effects are beneficial in those with autoimmune conditions such as lupus. However, astragalus should be used cautiously for the treatment of

autoimmune diseases or in conjunction with immunosuppressive therapies. Because immunostimulating polysaccharides may stimulate histamine release, allergic symptoms may be aggravated by the use of astragalus. This, however, has not been reported in the literature or from clinical use. According to the principles of TCM, astragalus should not be used during acute infectious conditions unless under the care of a qualified TCM practitioner.

Interactions

Both positive and negative interactions may occur. Astragalus potentiates the effects of acyclovir (53); IL-2, -20, -21; and rIFN-1 and -2 therapies (50,51). Because of its immunopromoting effects, astragalus may be incompatible with immunosuppressive agents in general.

Pregnancy, Mutagenicity, and Reproductive Toxicity

According to one review, astragalus is reported to have no mutagenic effects (54).

Lactation

Based on an authoritative review of the available pharmacologic and toxicologic literature, no limitation is to be expected (6,34,54).

Carcinogenicity

Studies suggest an anticarcinogenic activity.

Influence on Driving

Based on the available pharmacologic and toxicologic literature, no limitation is to be expected (6,34,54).

Overdose and Treatment

Specific data are lacking.

Toxicology

Based on a review of the available data and the experience of modern practitioners, astragalus can be considered a very safe herb even when taken within its large dosage range. Investigations of specific fractions including flavonoids, polysaccharide, and triterpene similarly show little toxicity (14,34,54).

Regulatory Status

In the United States, astragalus is regulated as a dietary supplement.

CONCLUSIONS

Astragalus is one of the most frequently used herbal medicines throughout Asia and is a very popular botanical used in western herbal supplements. In China, astragalus is used for a myriad of purposes relating to its high regard as a strengthening tonifier, immune modulator, anti-inflammatory, and anti-hepatotoxic. In the West, astragalus figures prominently in immune supportive formulas. Despite its popularity, there are few clinical trials regarding its use. There is some evidence to support the oral administration of astragalus for the prevention of colds and upper respiratory infections, and as an adjunct to conventional cancer therapies. These are very common

indications for which astragalus is applied by herbal practitioners. For its use in cancer therapies, there are no definitive guidelines. The modern experience of practitioners together with the limited clinical and preclinical data pointing to an immunomodulatory effect suggests that there may be some value for these indications, including the concomitant use of astragalus to reduce doxorubicin-induced immune suppression. However, more specific investigation in this area is needed.

Regarding its putative immunomodulating effects, the following mechanisms of action have been proposed: restoration of immune function, increased stem cell generation of blood cells and platelets, lymphocyte proliferation, rise in numbers of antibody-producing spleen cells, potentiation of rIL-2 and rIFN-1 and -2 immunotherapy, enhancement of phagocytic activity by macrophages and leukocytes, and increased cytotoxicity by NK cells.

Potential benefits to cardiovascular health, including relief from angina and congestive heart failure and improvement in clinical parameters following acute myocardial infarct, have been reported. Limited animal studies suggest that astragalus enhances coronary blood flow, may potentiate the release of nitric oxide, and potentiates the effects of endogenous antioxidant systems (e.g., SOD).

In Asia, astragalus is also used in conjunction with conventional medical treatments for hepatitis. Both animal and in vitro studies offer support for such treatment. As in the use of astragalus in cancer therapies, further clinical trials are required.

Though methodologically sound clinical trials for astragalus are generally lacking, natural health practitioners have a generally high regard for its use as a prophylactic against infectious disease and for its ability to build, maintain, and restore immunocompetency when used as a part of conventional cancer therapies. In addition to the very limited number of formal clinical studies that are available in English language sources, the published medical literature on astragalus has to be considered cautiously, as a number of the supporting studies utilize injectable preparations of isolated fractions that are not consistent with the oral use of astragalus supplements. Still, the existing data do support many of the traditional uses for which astragalus has been employed for centuries.

Bilberry

Marilyn Barrett

INTRODUCTION

Bilberry, *Vaccinium myrtillus* L., is a shrub with edible fruits that is native to Circumboreal regions from Europe to Asia as well as the Rocky Mountains in North America. Bilberries are related to other edible berries including blueberry, cranberry, huckleberry, and lingonberry. Bilberry fruits contain anthocyanins, which are natural pigments, responsible for the dark blue color of the fruits and for many of the health benefits. In vitro studies have shown that bilberry extracts have antioxidant activity, inhibit platelet aggregation, prevent degradation of collagen in the extravascular matrix surrounding blood vessels and joints, and have a relaxing effect on arterial smooth muscle. Bilberry extracts have also demonstrated anticancer and antibacterial actions, in vitro. Pharmacokinetic studies in animals and humans show that a small percentage of the anthocyanins is absorbed into the body and widely distributed. Human clinical studies have been conducted evaluating the potential benefits of bilberry preparations in treating venous insufficiency and visual disorders ranging from night vision to diabetic retinopathy as well as cancer prevention. No serious toxicities have been associated with preparations of the fruits in animal screens and no serious side effects have been identified in humans.

BACKGROUND

Bilberries are edible fruits from *V. myrtillus* L. of the family Ericaceae. Bilberry is the standardized common name for the fruit in the United States, but the fruit is also known as European blueberry, huckleberry, and whortleberry (1). Related to bilberry, and in the same genus of *Vaccinium*, are other edible berries including blueberry, cranberry, huckleberry, and lingonberry.

Bilberry is a shrub, 1–6 dm high, found in heaths, meadows, and moist coniferous forests in Circumboreal regions from Europe to Asia, with populations in the American and Canadian Rocky Mountains (2).

The blue-black berries are harvested when ripe, usually during the months of July through September. The berries are oblate-globose, 5–9 mm diameter, with 4–5 locules containing many seeds. The seeds are approximately 1 mm long with a yellow/brown-dimpled surface (2).

Both the leaves and fruits of bilberry have been used medicinally since the Middle ages.

The leaves were used topically for inflammation, infections, and burns, as well as internally as a treatment for diabetes. According to the herbalist Grieve, the fruits were

used to treat dysentery, diarrhea, gastrointestinal inflammation, hemorrhoids, vaginal discharges, scurvy, urinary complaints, and to dry up breast milk. More recently, it was found that bilberry was used by World War II pilots to improve their night vision (2,3).

Bilberry fruit preparations are still used to improve vision as well as for their benefits to the circulatory system: treating fragility and altered permeability of blood vessels that is either primary or secondary to arterial hypertension, arteriosclerosis, or diabetes (3).

CHEMISTRY AND PREPARATION

Bilberry fruits contain anthocyanins that are natural pigments in the chemical class known as flavonoids. Anthocyanins are glycosides or compounds with sugars attached at the 3 position, while anthocyanidins are aglycones (the same basic structure without the sugars attached) (see chapter 74, "Polyphenol Overview"). The majority (64%) of anthocyanins in the fruit are glycosides of cyanidin and delphinidin (Fig. 1). The quantity of anthocyanin in the fruit ranges from 300 to 700 mg per 100 g. Bilberry fruits also contain flavonols, tannins, phenolic acids, organic acids, sugars, vitamins, and volatile compounds (2).

The primary commercial source of bilberry fruits is "wild harvest" from regions in Europe and Scandinavia. The fruits are sold fresh, frozen, or dried. Besides the whole fruit, commercial products include cold macerates, decoctions, and dry extracts. The dry extracts are commonly prepared using alcohol, methanol or ethanol (2).

Until recently, a single-wavelength spectrophotometric technique (UV) was commonly used to standardize the anthocyanin content of bilberry products. However, this technique did not detect adulteration of bilberry preparations with substances of similar color (4). A high-performance liquid chromatographic technique that can detect and quantitate both anthocyanins and anthocyanidins has recently been developed enabling a better assurance of product identity and quality (5).

Most studies on bilberry have been conducted using extracts characterized as containing 36% anthocyanins or 25% anthocyanidins.

PRECLINICAL STUDIES

In vitro studies have shown that bilberry extracts have antioxidant activity, inhibit platelet aggregation, prevent

Figure 1 Chemical structures of anthocyanins.

degradation of collagen in the extravascular matrix surrounding blood vessels and joints, and have a relaxing effect on arterial smooth muscle. These actions are vaso-protective, increasing capillary resistance and reducing capillary permeability (3). Bilberry extracts have also demonstrated anticancer and antibacterial actions *in vitro*. There is no evidence of toxicity in animals at the effective doses.

Antioxidant Activity

Bilberry fruits have demonstrated antioxidant activity *in vitro* and in animal models. In the oxygen radical absorbance capacity (ORAC) assay, an *in vitro* test measuring free radical quenching, bilberry fruits had potent activity compared with other fresh fruits and vegetables ($44.6 \pm 2.3 \mu\text{mol Trolox equivalents (TE)/g}$) (6). In another assay, a bilberry extract (25% anthocyanins) exhibited antioxidant activity in protecting keratinocytes in culture from damage due to UVA and UVB light (7,8). The bilberry extract attenuated UVA-induced reactive oxygen species formation, peroxidation of membrane lipids, and depletion of intracellular glutathione in concentrations of 10–50 mg/L (7). In the same concentration range, the extract inhibited UVB-induced generation of reactive oxygen and nitrogen species, DNA strand breaks, as well as caspase-3 and capase-9 activity (mediators that execute apoptotic cell death) (8).

In an animal study, a bilberry extract characterized as containing 38% anthocyanins reduced oxidative stress caused in mice by removal of the animal's whiskers. The extract administered orally at a dose of 100 mg/kg for 7 days ameliorated the increase in oxygen radicals (thio-barbituric acid reactive substances), protein carbonyl formation, and lipid peroxidation in the brain, heart, kidney, and liver. The extract also suppressed the stress-induced changes in dopamine levels (9).

A bilberry extract (42% anthocyanins) reduced oxidative stress to the liver in a restraint-stress mouse model. The extract, administered at a dose of 200 mg/kg for 5 days, ameliorated the increase in plasma levels of alanine aminotransferase, a liver enzyme. The extract also reduced plasma and liver ORAC levels and increased plasma glutathione and vitamin C levels in the liver (10). A similar study was conducted in mice with kidney damage in-

duced by potassium bromate. Oral administration of the same extract ameliorated the increase in blood urea nitrogen levels and the decreases in kidney malondialdehyde, nitric oxide, and xanthine oxidase levels. The bilberry extract also improved the kidney ORAC levels (11).

MyrtoSelectTM, an extract containing approximately 40% anthocyanins, was tested for its effects on gene expression (DNA microarray) in a macrophage cell line stimulated with lipopolysaccharide (LPS). The extract, at a concentration of 75 $\mu\text{g/mL}$, appeared to mitigate the effect of LPS, targeting genes involved in inflammation and immune defense. Pretreatment with the bilberry extract affected 45% of the genes downregulated by LPS and 36% of genes upregulated by LPS (12).

Circulation

Bilberry extracts have demonstrated beneficial effects on the circulation, including inhibiting platelet aggregation, reducing capillary permeability, facilitating vasodilation, and inhibiting the development of atherosclerosis and angiogenesis.

Myrtocyan[®] (also known as MirtoSelectTM, containing 36% anthocyanins) inhibited platelet aggregation *in vitro* induced by adenosine diphosphate (ADP), collagen, and sodium arachidonate in rabbit platelet-rich plasma with IC_{50} values ranging from 0.36 to 0.81 mg/mL. Myrtocyan administered orally to rats (400 mg/kg) prolonged the bleeding time in the animals, without affecting coagulation pathways. The same dose administered to mice reduced the adhesiveness of platelets to glass (3). Myrtocyan administered to healthy human subjects, 480 mg/day (173 mg anthocyanins/day) for 30–60 days, reduced the aggregation response *ex vivo* to ADP and collagen (13).

In a rabbit skin model, oral treatment with 400 mg anthocyanins per kilogram body weight 30 minutes before topical application of chloroform reduced the capillary permeability caused by the irritant by 66%. In rats, administration of bilberry anthocyanins, 200 mg/kg orally, decreased bradykinin-induced capillary permeability by 39%. The same dose reduced carrageenin-induced rat paw edema by 45% (14). In a rat model of experimentally induced hypertension, 500 mg anthocyanins per kilogram body weight given orally for 12 days completely ameliorated the increase in blood–brain barrier permeability and reduced the increase in aortic vascular permeability by 40% (15). In a hamster cheek pouch model, 100 mg bilberry extract per kilogram daily for 4 weeks reduced the circulatory damage due to ischemic reperfusion (16). A rat model suggested that bilberry anthocyanins (50 mg/kg IP) inhibited the enzymatic degradation of collagen, decreasing the permeability of the blood–brain barrier caused by proteases (17).

Bilberry preparations are reported to relax arterial tissues *in vitro*. Preliminary experiments pointed to a mechanism involving prostaglandins. However, a more recent study using porcine coronary arteries demonstrated a mechanism involving nitric oxide (endothelial-derived relaxing factor) (18).

A bilberry extract was reported to inhibit the development of atherosclerosis in apolipoprotein E-deficient mice. The mice received diets supplemented with 0.02% of a bilberry extract (52% anthocyanins) for 16 weeks. The

extract reduced lipid deposits and the development of lesions. It did not affect plasma antioxidant capacity or plasma lipid levels (19).

A bilberry extract (25% anthocyanins) was tested for its effect on angiogenesis both in vitro and in vivo. The extract at concentrations of 0.3–30 µg/mL inhibited tube formation and the migration of human umbilical vein endothelial cells induced by vascular endothelial growth factor A. The extract also inhibited the induction of retinopathy in newborn mice, which was induced with oxygen. Intravitreal administration of 300 ng extract per eye significantly inhibited the area of neovascular tufts (20).

Anticancer

Anthocyanins have been reported to mediate several physiological functions that ultimately may result in cancer suppression. Anthocyanins suppress the growth of cancer cell lines in vitro, including HL60 human leukemia cells and HCT116 human colon cancer cells. A bilberry extract induced apoptotic cell bodies and nucleosomal DNA fragmentation in HL60 cells (21). A bilberry extract (Mirtocyan) has also been shown to suppress the activity of receptor tyrosine kinases, which are thought to play a crucial role in carcinogenesis and tumor progression. When tested over a number of tyrosine kinases, the activity was consistent but not specific (22).

Antibacterial

Phenolic compounds in bilberry have demonstrated in vitro antimicrobial effects against strains of *Salmonella* and *Staphylococcus* possibly through interfering with adhesion of the bacteria. Treatment of bilberry preparations with pectinase released phenolics from the cell wall matrix and increased the antibacterial activity (23). In experiments with *Neisseria meningitidis*, the bacteria that causes meningitis and septicemia, a bilberry juice fraction was reported to inhibit the binding of the bacteria to epithelial cells in culture. Fractions of the juice also bound to the bacterial pili. The authors concluded that anthocyanins were partly responsible for the activity but that there appeared to be other compounds in bilberry that may also interact directly with the pili or act synergistically with the anthocyanins (24).

Safety Studies (Animal Toxicology)

Myrtocyan (25% anthocyanins) has been tested for acute and chronic toxicity in animal studies. There were no deaths with an acute dose in rats up to 20 g/kg orally and in mice up to 25 g/kg. Six months treatment with doses of 125–500 mg/kg in rats and 80–320 mg/kg in dogs found no evidence of toxicity. The preparation was tested in guinea pigs for 2 weeks and in rats for 6 weeks with doses up to 43 mg/kg without incident (2,3).

PHARMACOKINETICS

Animal studies show that bilberry anthocyanins are absorbed intact, or after methylation. This is unlike other flavonoid glycosides which are hydrolyzed to their aglycones and metabolized to glucuronidated or sulfated

derivatives (25). Following administration of 400 mg/kg orally to rats, peak blood levels of anthocyanins were detected within 15 minutes and afterwards declined rapidly. Only 1% of the anthocyanins was eliminated in the urine and 4% in the bile. The absolute bioavailability of bilberry anthocyanins was estimated to be 1.2–5% (26). A study in mice reported that malvidin 3-glucoside and malvidin 3-galactoside were the principal anthocyanins in the plasma 60 minutes after oral administration of 100 mg/kg. When the mice were maintained on a diet containing 0.5% bilberry extract, plasma levels of anthocyanins reached 0.26 µM. Anthocyanidins were detected in the liver, kidney, and lung. They were not detected in the spleen, thymus, heart, muscle, brain, white fat, or eyes (25).

A pharmacokinetic study with six human subjects detected anthocyanins in the plasma 1.5–6 hours following intake of a bilberry–lingonberry puree. The study examined the production of urinary phenolic acids and found the greatest increase in methylated compounds. The amount of urinary phenolic acids was low, and the authors suggested that the fragmentation of anthocyanins to phenolic acids was not a major metabolic pathway (27). Another pharmacokinetic study with 20 subjects that consumed 100 g/day of berries, including black currant, lingonberries, and bilberries, for 8 weeks reported an increase in serum quercetin (up to 51% higher) compared with control subjects who did not consume berries (28). A study with 25 subjects administered 1.4–5.6 g Mirtocyan (25% anthocyanins) daily for 7 days reported detection of anthocyanins as well as methyl and glucuronide metabolites in the plasma and urine but not in the liver (29).

CLINICAL STUDIES

Human clinical studies have been conducted evaluating the potential benefits of bilberry preparations in treating venous insufficiency and visual disorders ranging from night vision to diabetic retinopathy as well as cancer prevention.

Vascular Health

Clinical studies have been conducted evaluating the potential benefits of bilberry preparations in treating venous insufficiency. A review of studies conducted between 1970 and 1985 included 568 patients with venous insufficiency of the lower limbs who were treated with bilberry preparations (30). The studies reported an improvement in circulation and in lymph drainage resulting in a reduction in edema. A more recent placebo-controlled study which included 60 participants with varicose veins reported improvement in edema in the legs and ankles, sensation of pressure, cramps, and tingling or “pins and needles” sensations with a dose of 160 mg Tegens®, three times daily for 1 month (31). Tegens (Inverni della Beffa, Italy) contains a bilberry extract named Myrtocyan or MirtoSelect (25% anthocyanins), manufactured by Indena SpA, Italy.

Visual Health

A systematic review was conducted on placebo-controlled studies on the effects of bilberry preparations on night

vision. Literature searches identified 30 clinical studies, and 12 of those met the inclusion criteria of being placebo controlled. Of the 12 studies, 5 were randomized. Healthy subjects with normal or above average eyesight were tested in 11 out of the 12 studies. Many of the studies were acute, using a single dose, and the longest treatment period was 28 days. Full characterization of the products used in the studies was not available, but assuming 25% anthocyanin content, the doses of anthocyanin ranged from 12 to 2880 mg. The techniques used to measure the extent and rate of dark adaptation ranged from visual acuity, contrast sensitivity, and critical flicker fusion to electroretinographic monitoring of response to light flashes. The four most recent randomized controlled studies with rigorous methodology reported negative results. One randomized controlled study and all seven of the non-randomized studies reported positive effects. The authors concluded that the present studies do not support the use of bilberry by those who are healthy with normal vision to improve their night vision. However, uncontrolled studies report a benefit for those with eye disorders, including retinal degeneration, myopia, simple glaucoma, and pathological fundus. Furthermore, studies with synthetic anthocyanins suggest a positive benefit for those with myopia, central retinal lesions, and night blindness (32).

Two studies on diabetic retinopathy, using a dose of 160 mg Tegens twice daily, demonstrated a trend toward improvement in mild cases of the disease. The first study was a 1-month, placebo-controlled study that included 36 subjects. At the end of the month, 10 of 13 patients in the Tegens group with ophthalmoscopically detectable retinal abnormalities (microaneurisms, hemorrhagic foci, exudates) were improved, while all 15 patients with these abnormalities in the placebo group remained unchanged. A similar trend was observed among those patients with fluoroangiographic abnormalities (33). The second study lasted 1 year and included 40 subjects who were given Tegens or placebo in addition to the usual therapy for retinopathy. As a result, in 50% of patients given bilberry, the retinal lesions and associated edema were improved compared with 20% in the control group (34).

A mixture of vitamin E and bilberry (FAR-1, Ditta Farmigea SpA, Italy) showed a trend toward prevention of senile cataracts after 4 months of 180 mg bilberry anthocyanins (25% anthocyanidins) and 100 mg DL-tocopheryl acetate twice daily. When the placebo group was changed from placebo to the bilberry preparation, and the trial continued for an additional 4 months, there was no statistical difference between the two groups. The rationale for this study was previous indications that antioxidants might prevent the development of senile cataracts (35).

A mechanistic study using Myrtocyan examined changes in pupillary reflexes to light following a single high dose of 240 mg anthocyanosides or placebo in 40 healthy volunteers. The study was conducted to explore the use of bilberry in work situations where exposure to high light intensities dampens pupillary reflexes and leads to vision fatigue. The authors of the study suggested that the pigments in bilberry might increase sensitivity to light and improve blood flow in the capillaries of the eye. Improvement in pupillary reflexes was observed

in both groups, with the improvement in the treatment group being only slightly better than that in the placebo group (36).

Cancer Prevention

In an open label study, 25 colorectal cancer patients scheduled to undergo surgery were given 1.4, 3.8, or 5.6 g bilberry extract (Mirtocyan) containing 0.2–2.0 g anthocyanins for 7 days before surgery. Availability of anthocyanins was determined by detection in the plasma, colorectal tissue, and urine but not in the liver. Anthocyanins detected in the body were unaltered, or products of metabolic glucuronidation and *O*-methylation. Proliferation of cells in the tumor tissue was decreased by 7% compared with before the bilberry intervention (29).

Side Effects and Adverse Effects

No side effects were reported in the clinical studies mentioned earlier. In a 1987 postmarketing surveillance study with 2295 subjects, only 94 (4.1%) complained of minor side effects, most of which involved the gastrointestinal track. Most of the participants took 160 mg Tegens twice daily for 1–2 months (3).

Observed Drug Interactions and Contraindications

No drug interactions or contraindications have been reported in the literature for bilberry.

CONCLUSIONS

Bilberry fruit extracts and anthocyanins have been the subject of pharmacological studies and human clinical trials. In vitro and in vivo studies demonstrate good evidence for the antioxidant activity of bilberry extracts along with strong indications of benefit to the cardiovascular system. Animal and human pharmacokinetic studies demonstrate bioavailability of anthocyanins, but absorption appears to be limited. Human clinical studies on the effects of bilberry extracts on eyesight and vascular diseases suffer from poor methodology, including small sample sizes and short-term exposures. While it appears doubtful that bilberry preparations benefit the night vision of healthy subjects, the benefit for those with diabetic retinopathy and other eye disorders merits exploration. Another area that appears promising is that of benefits to the cardiovascular system, specifically vasculitis or venous insufficiency. Bilberry products have been safely consumed, without significant adverse events or side effects.

REGULATORY STATUS

Bilberry is a food and preparations are also used medicinally. In the United States, preparations of bilberry are sold as foods and dietary supplements. The U.S. Pharmacopoeia has published a standard monograph for powdered bilberry extract (37). The German Commission E completed a monograph for bilberry fruits in which preparations of the ripe fruit are indicated orally for

nonspecific, acute diarrhea and topically for mild inflammation for the oral and pharyngeal mucosa (38). The European Scientific Cooperative on Phytotherapy (ESCOP) monograph lists the internal use of bilberry fruit preparations (enriched in anthocyanins) for symptomatic treatment of problems related to varicose veins, such as painful and heavy legs. The ESCOP monograph also lists the dried fruit as supportive treatment of acute, nonspecific diarrhea (39). In Canada, bilberry products are approved as natural health products for traditional use orally as an astringent and as a source of antioxidants as well as for use as a gargle to relieve mild inflammation of the mouth and/or throat (40).

Biotin

Donald M. Mock

INTRODUCTION

Biotin is usually classified as a B-complex vitamin. "Biotin" is by far the most widely used term for this vitamin. However, discovery of biotin by different approaches has also led to names such as Bios IIB, protective factor X, vitamin H, coenzyme R, factor S, factor W, and vitamin B_W. This entry reviews the biochemistry of biotin and summarizes the clinical findings of deficiency. Readers are encouraged to use the references for further information.

SCIENTIFIC NAMES AND STRUCTURE

The molecular weight of biotin is 244.31 Da. The structure of biotin was elucidated independently by Kogl and du Vigneaud in the early 1940s and is shown in Figure 1 (1). Biotin is a bicyclic compound. The imidazolidone contains an ureido group (–N–CO–N–). The tetrahydrothiophene ring contains sulfur and has a valeric acid side chain attached to the C2 carbon of the sulfur-containing ring. This chain has a *cis* configuration with respect to the ring that contains the nitrogen atoms. The two rings are fused in the *cis* configuration, producing a boat-like structure. With three asymmetric carbons, eight stereoisomers exist; only one [designated D-(+)-biotin or, simply, biotin] is found in nature and is active when covalently joined via an amide bond between the carboxyl group of the valeric acid side chain of biotin and the ε-amino group of a lysine residue of an apocarboxylase. Biocytin (ε-*N*-biotinyl-L-lysine) is the product of digestion of protein-bound dietary biotin and cellular turnover of biotin-containing carboxylases and histones; biocytin is as active as biotin on a molar basis in mammalian growth studies.

Goldberg/Sternbach synthesis or a modification thereof is the method by which biotin is synthesized commercially (1). Additional stereospecific methods have been published (2,3).

HISTORY

Biotin was discovered in nutritional experiments that demonstrated a factor present in many foodstuffs that was capable of curing the scaly dermatitis, hair loss, and neurologic signs induced in rats fed dried egg white. Avidin, a glycoprotein found in egg white, binds biotin very specifically and tightly. From an evolutionary standpoint, avidin probably serves as a bacteriostat in egg white. Consistent with this hypothesis is the observation that avidin is resistant to a broad range of bacterial proteases in both free and biotin-bound form. Because avidin is also resistant to

pancreatic proteases, dietary avidin binds to dietary biotin (and probably any biotin from intestinal microbes) and prevents absorption, carrying the biotin on through the gastrointestinal tract.

Biotin is definitely synthesized by intestinal microbes; however, the contribution of microbial biotin to absorbed biotin, if any, remains unknown. Cooking denatures avidin, rendering this protein susceptible to pancreatic proteases and unable to interfere with the absorption of biotin.

BIOCHEMISTRY

Biotin acts as an essential cofactor for five mammalian carboxylases. Each has the vitamin covalently bound to a polypeptide. For monomeric carboxylases, this polypeptide is the apocarboxylase. For the dimeric carboxylases, this monomer with a biotinylation site is designated the chain. The covalent attachment of biotin to the apocarboxylase protein is a condensation reaction catalyzed by holocarboxylase synthetase (EC 6.3.4.10). These apocarboxylase regions contain the biotin motif (methionine-lysine-methionine), a specific sequence of amino acids present in each of the individual carboxylases; this sequence tends to be highly conserved within and between species. One interpretation concerning conservation of this amino acid sequence is that these residues allow the biotinylated peptide to swing the carboxyl (or acetyl) group from the site of activation to the receiving substrate.

All five of the mammalian carboxylases catalyze the incorporation of bicarbonate as a carboxyl group into a substrate and employ a similar catalytic mechanism. In the carboxylase reaction, the carboxyl moiety is first attached to biotin at the ureido nitrogen opposite the side chain. Then the carboxyl group is transferred to the substrate. The reaction is driven by the hydrolysis of ATP to ADP and inorganic phosphate. Subsequent reactions in the pathways of the five mammalian carboxylases release CO₂ from the product of the enzymatic reaction. Thus, these reaction sequences rearrange the substrates into more useful intermediates but do not violate the classic observation that mammalian metabolism does not result in the net fixation of carbon dioxide (4).

The five carboxylases are pyruvate carboxylase (EC 6.4.1.1), methylcrotonyl-CoA carboxylase (EC 6.4.1.4), propionyl-CoA carboxylase (EC 6.4.1.3), and two isoforms of acetyl-CoA carboxylase (EC 6.4.1.2), denoted I and II, which are also known as ACC and β ACC. Each

Figure 1 Protein-bound biotin with arrow showing the amide bond to the ϵ -amino acid.

carboxylase catalyzes an essential step in intermediary metabolism (Fig. 2).

Pyruvate carboxylase mediates in the incorporation of bicarbonate into pyruvate to form oxaloacetate, an intermediate in the Krebs tricarboxylic acid cycle. Thus, pyruvate carboxylase catalyzes an anaplerotic reaction. In gluconeogenic tissues (i.e., liver and kidney), the oxaloacetate can be converted to glucose. Deficiency of this enzyme (denoted by a block in the metabolic pathway) is likely the cause of the lactic acidosis and hypoglycemia observed in biotin-deficient animals and humans.

Methylcrotonyl-CoA carboxylase catalyzes an essential step in the degradation of the branch-chained

amino acid leucine. Deficient activity of this enzyme leads to metabolism of 3-methylcrotonyl CoA to 3-hydroxyisovaleric acid and 3-methylcrotonylglycine by an alternate pathway. Thus, increased urinary excretion of these abnormal metabolites reflects deficient activity of this carboxylase.

Propionyl-CoA carboxylase catalyzes the incorporation of bicarbonate into propionyl CoA to form methylmalonyl CoA, which undergoes isomerization to succinyl CoA and enters the tricarboxylic acid cycle. In a fashion analogous to methylcrotonyl-CoA carboxylase deficiency, inadequacy of this enzyme leads to increased urinary excretion of 3-hydroxypropionic acid and 3-methylcitric acid and enhanced accumulation of odd-chain fatty acids C15:0 and C17:0. The mechanism is likely the substitution of propionyl CoA for acetyl CoA during fatty acid elongation. Although the proportional increase is large (e.g., 2- to 10-fold), the absolute composition relative to other fatty acids is quite small (<1%) and likely produces little or no functional consequences.

Acetyl-CoA carboxylases, I and II both, catalyze the incorporation of bicarbonate into acetyl CoA to form malonyl CoA. Acetyl-CoA carboxylase I is located in the cytosol and produces cytosolic malonyl CoA, which is rate limiting in fatty acid synthesis (elongation). Acetyl-CoA carboxylase II is present on the outer mitochondrial membrane. As demonstrated by the pioneering work of Wakil and colleagues, acetyl-CoA carboxylase II controls a separate mitochondrial pool of malonyl CoA that, in turn, controls fatty acid oxidation in mitochondria through the inhibitory effect of malonyl CoA on fatty acid transport into mitochondria.

Figure 2 Pathways involving biotin-dependent carboxylases. Deficiencies (hatched bar) of pyruvate carboxylase, propionyl-CoA carboxylase, methylcrotonyl-CoA carboxylase, and acetyl-CoA carboxylase lead to increased blood concentrations and urinary excretion of characteristic organic acids denoted by ovals.

In the normal turnover of cellular proteins, holocarboxylases are degraded to biocytin or biotin linked to an oligopeptide containing at most a few amino acid residues. Because the amide bond between biotin and lysine (Fig. 1) is not hydrolyzed by cellular proteases, the specific hydrolase biotinidase [biotin amide hydrolase (EC 3.5.1.12)] is required to release biotin for recycling.

Biotin exists in free and bound pools within the cell that are responsive to changes in its status (5). The pool size is likely determined by a balance between cellular uptake and cellular release, incorporation into apocarboxylases and histones, release from these biotinylated proteins during turnover, and catabolism to inactive metabolites. Regulation of intracellular mammalian carboxylase activity by biotin remains to be elucidated.

Genetic deficiencies of holocarboxylase synthetase and biotinidase cause the two distinct types of multiple carboxylase deficiency that were previously designated the neonatal and juvenile forms. The genes for holocarboxylase synthetase and human biotinidase have been cloned, sequenced, and characterized (6). The gene coding for holocarboxylase synthetase is located on chromosome 21q22.1 and consists of 14 exons and 13 introns in a span of 240 kilobase (kb). Studies of human mutant holocarboxylase synthetase indicate that all forms of holocarboxylase synthetase are likely encoded by one gene. Biotinidase deficiency is particularly relevant to understanding biotin inadequacy because the clinical manifestations appear to result largely from secondary biotin depletion.

PHYSIOLOGY

Digestion of Protein-Bound Biotin

The content of free and protein-bound forms of biotin in foods is variable, but the majority in meats and cereals appear to be protein bound via an amide bond between biotin and lysine. Neither the mechanisms of intestinal hydrolysis of protein-bound biotin nor the determinants of bioavailability have been clearly delineated. Wolf et al. (7) have postulated that biotinidase plays a critical role in the release of biotin from covalent binding to protein. Doses of free biotin that do not greatly exceed the estimated dietary intake (e.g., 50–150 µg/day) appear adequate to prevent the symptoms of biotinidase deficiency. This suggests that biotinidase inadequacy in patients causes biotin deficiency, at least in part, through impaired intestinal digestion of protein-bound biotin.

Intestinal Absorption

At physiologic pH, the carboxylate group of biotin is negatively charged. Thus, the vitamin is at least modestly water soluble and requires a transporter to cross the membranes of enterocytes for intestinal absorption, of somatic cells for utilization, and of renal tubule cells for reclamation from the glomerular filtrate.

An excellent in-depth review of intestinal uptake of biotin has been published recently (8). Two biotin transporters have been described: (i) a multivitamin transporter present in many tissues including the intestine and (ii) a biotin transporter identified in human lymphocytes.

The transporter responsible for absorption of free biotin in the small and large intestine is saturable and Na⁺

dependent. The transporter also transports pantothenic acid and lipoate and is deemed the sodium-dependent multivitamin transporter (SMVT). SMVT was discovered in 1997 by Prasad et al. (9) in human placental choriocarcinoma cells. This transporter is widely expressed in human tissues (10). SMVT system has been cloned and demonstrated to be exclusively expressed at the apical membrane of enterocytes. SMVT is the main biotin uptake system that operates in human intestinal epithelial cells. The 5'-regulatory region of the SMVT gene has also been cloned and characterized both in vitro and in vivo (8). Intestinal biotin uptake is adaptively upregulated in biotin deficiency via a transcriptionally mediated mechanism that involves KLF4 sites. The cytoplasmic C-terminal domain of the polypeptide is essential for its targeting to the apical membrane domain of epithelial cells (8).

In rats, biotin transport is upregulated during maturation after weaning and by biotin deficiency (11). Carrier-mediated transport of the vitamin is most active in the proximal small bowel of the rat and humans (8). However, absorption from the proximal colon is still significant, supporting the potential nutritional significance of biotin synthesized and released by enteric flora (11). Clinical studies have provided some evidence that biotin is absorbed from the human colon (12). In contrast, more rigorous studies in swine indicate that biotin absorption from the hindgut is much less efficient than that from the upper intestine; furthermore, biotin synthesized by enteric flora may not present at a location or in a form in which bacterial biotin contributes importantly to absorbed biotin.

Exit of biotin from the enterocyte (i.e., transport across the basolateral membrane) is also carrier mediated (11). However, basolateral transport is independent of Na⁺, is electrogenic, and does not accumulate biotin against a concentration gradient.

Transport in Blood

Biotin dissolved in blood is carried from the site of absorption in the intestine to the peripheral tissues and the liver (1). Wolf et al. (13) originally hypothesized that biotinidase might serve as a biotin-binding protein in plasma or perhaps even as a carrier protein for the movement of biotin into the cell. Based on protein precipitation and equilibrium dialysis using ³H-biotin, Chauhan and Dakshinamurti (14) concluded that biotinidase is the only protein in human serum that specifically binds biotin. However, using ³H-biotin, centrifugal ultrafiltration, and dialysis to assess reversible binding in plasma from the rabbit, pig, and human, Mock and Lankford (15) found that less than 10% of the total pool of free plus reversibly bound biotin is reversibly bound to plasma protein; the biotin binding observed could be explained by binding to human serum albumin. Using acid hydrolysis and ³H-biotinyl-albumin, Mock and Malik (16) found additional biotin covalently bound to plasma protein. The percentages of free, reversibly bound, and covalently bound biotin in human serum are approximately 81%, 7%, and 12%. A biotin-binding immunoglobulin has been identified in human serum. An approximately fivefold higher concentration of this biotin-binding immunoglobulin was reported in patients with Graves disease than in normal and healthy controls (17). The role of plasma

proteins in the transport of biotin remains to be definitively established.

Biotin concentrations in erythrocytes are equal to those in plasma (D.M. Mock, unpublished observation). However, transport into erythrocytes is very slow, consistent with passive diffusion (18).

Uptake by the Liver

Studies in a variety of hepatic cell lines indicate that uptake of free biotin by the liver is similar to intestinal uptake and is mediated by SMVT (19–21). Transport is mediated by a specialized carrier system that is Na^+ dependent, electroneutral, and structurally specific for a free carboxyl group. At large concentrations, movement is carried out by diffusion. Metabolic trapping, for example, biotin bound covalently to intracellular proteins, is also important. After entering the hepatocyte, biotin diffuses into the mitochondria via a pH-dependent process.

The biotin transporter identified in lymphocytes is also Na^+ coupled, saturable, and structurally specific (22). Recent studies by Daberkow and coworkers provide evidence in favor of monocarboxylate transporter 1 as the lymphocyte biotin transporter (23).

A child with biotin dependence due to a defect in the lymphocyte biotin transporter has been reported (18). The child became acutely encephalopathic at the age of 18 months. Urinary organic acids indicated deficiency of several biotin-dependent carboxylases. Symptoms improved rapidly following biotin supplementation. Serum biotinidase activity and biotinidase gene sequence were normal. Activities of biotin-dependent carboxylases in lymphocytes and cultured skin fibroblasts were normal, excluding biotin holocarboxylase synthetase deficiency as the cause. Despite extracellular biotin sufficiency, biotin withdrawal caused recurrence of abnormal organic aciduria, indicating intracellular biotin deficiency. Biotin uptake rates into fresh lymphocytes from the child and into his or her lymphocytes transformed with Epstein-Barr virus were about 10% of normal fresh and transformed control cells, respectively. For fresh and transformed lymphocytes from his or her parents, biotin uptake rates were consistent with heterozygosity for an autosomal recessive genetic defect. *SMVT* gene sequence was normal; regulatory regions of the *SMVT* gene have not been characterized. These investigators speculated that lymphocyte biotin transporter is expressed in additional tissues such as the kidney and may mediate some critical aspect of biotin homeostasis, but the complete molecular etiology of this child's biotin transporter deficiency remains to be elucidated.

Ozand et al. (24) recently described several patients in Saudi Arabia with biotin-responsive basal ganglia disease. Symptoms include confusion, lethargy, vomiting, seizures, dystonia, dysarthria, dysphagia, seventh nerve paralysis, quadriparesis, ataxia, hypertension, chorea, and coma. A mutation in *SLC19A3* was identified, and defect in the biotin transporter system across the blood-brain barrier was postulated (25). However, in an elegant set of experiments, Said and coworkers demonstrated that *SLC19A3* is the apical thiamine transporter and renamed *SLC19A3* appropriately as *THTR2* (26), in contrast to the basolateral thiamine transporter *THTR1*. The explanation

for the documented biotin responsiveness of these patients remains unknown.

Renal Handling

Specific systems for the reabsorption of water-soluble vitamins from the glomerular filtrate contribute importantly to conservation of these vitamins (27). Animal studies using brush border membrane vesicles from human kidney cortex indicate that biotin is reclaimed from the glomerular filtrate against a concentration gradient by a saturable, Na^+ -dependent, structurally specific system (28). Using human-derived proximal tubular epithelial HK-2 cells as a model, Said and coworkers demonstrated that biotin uptake by human renal epithelial cells occurs via the SMVT system and that the process is regulated by intracellular protein kinase C and Ca^{++} /calmodulin-mediated pathways (29). The uptake process is adaptively regulated by extracellular biotin concentrations via transcriptional regulatory mechanisms (29) consistent with previous studies demonstrating reduced biotin excretion early in experimentally induced biotin deficiency in human subjects (30,31).

Subsequent egress of biotin from the tubular cells occurs via a basolateral membrane transport system that is not dependent on Na^+ . Biocytin does not inhibit tubular reabsorption of biotin (28). Studies in patients with biotinidase deficiency suggest that there may be a role for biotinidase in the renal handling of biotin (32,33).

Transport into the Central Nervous System

A variety of animal and human studies suggest that biotin is transported across the blood-brain barrier (1,34,35). The transporter is saturable and structurally specific for the free carboxylate group on the valeric acid side chain. Transport into the neuron also appears to involve a specific transport system as well as subsequent trapping of biotin by covalent binding to brain proteins, presumably the biotin-dependent carboxylases and histones.

Recently, concentrations of biotin were determined initially as total avidin-binding substances in cerebrospinal fluid (CSF) from 55 children, and biotin, biotin sulfoxide, and bisnorbiotin were quantitated by high-performance liquid chromatography (HPLC) and avidin-binding assay in CSF samples from a subset of 11 children (36). Concentrations of total avidin-binding substances averaged 1.6 nmol/L with substantial variability, $\text{SD} = 1.3$ nmol/L. CSF concentrations of biotin and biotin analogs varied widely, but substantial amounts of biotin sulfoxide were detected in every sample. Of the total, biotin accounted for $42\% \pm 16\%$, biotin sulfoxide for $41\% \pm 12\%$, and bisnorbiotin for $8\% \pm 14\%$. Surprisingly, the molar sum of biotin plus biotin sulfoxide and bisnorbiotin on average exceeded the total avidin-binding substances concentrations from the same CSF sample by >200 -fold. These investigators found no masking of detection or degradation of biotin or biotin sulfoxide. Gel electrophoresis and streptavidin Western blot detected several biotinylated proteins in CSF leading to the conclusion that biotin is bound to protein covalently, reversibly, or both; they speculated that biotin bound to protein likely accounts for the increase in detectable biotin after HPLC and that

protein-bound biotin plays an important role in biotin nutrition of the brain.

Placental Transport

Biotin concentrations are 3- to 17-fold greater in plasma from human fetuses compared with their mothers in the second trimester, consistent with active placental transport (37). Specific systems for transport of biotin from the mother to the fetus have been reported recently (10,38–40). The microvillus membrane of the placenta contains a saturable transport system for biotin that is Na⁺ dependent and actively accumulates biotin within the placenta, consistent with SMVT (10,38–40).

Transport into Human Milk

More than 95% of the biotin is free in the skim fraction of human milk (41). The concentration of biotin varies substantially in some women (42) and exceeds that in serum by one to two orders of magnitude, suggesting that there is a transport system into milk. The biotin metabolite bisnorbiotin (see discussion of metabolism under pharmacology section) accounts for approximately 50%. In early and transitional human milk, the biotin metabolite and biotin sulfoxide accounts for about 10% of the total biotin plus metabolites (43). With postpartum maturation, the biotin concentration increases, but the bisnorbiotin and biotin sulfoxide concentrations still account for 25% and 8% at 5 weeks postpartum. The concentration of biotin in human milk exceeds the plasma concentration by 10- to 100-fold, implying that a transport system exists. Current studies provide no evidence for a soluble biotin-binding protein or any other mechanism that traps biotin in human milk. The location and the nature of the biotin transport system for human milk have yet to be elucidated.

PHARMACOLOGY

Studies in which pharmacologic amounts of biotin were administered orally and intravenously to experimental subjects and tracer amounts of radioactive biotin were administered intravenously to animals show that biotin in pure form is 100% bioavailable when administered orally. The preponderance of dietary biotin detectable by bioassays is bound to carboxylases and perhaps to histones. The bioavailability of biotin from foodstuffs is not known, whereas that from animal feeds varies but can be well below 50%. After intravenous administration, the vitamin disappears rapidly from plasma; the fastest phase of the three-phase disappearance curve has a half-life of less than 10 minutes.

An alternate fate to being covalently bound to protein (e.g., carboxylases) or excretion unchanged in urine is catabolism to an inactive metabolite before excretion in urine (4). About half of biotin undergoes metabolism before excretion. Two principal pathways of biotin catabolism have been identified in mammals. In the first pathway, the valeric acid side chain of biotin is degraded by β -oxidation. This leads to the formation of bisnorbiotin, tetranorbiotin, and related intermediates

Table 1 Normal Range of Urinary Excretion of Biotin and Major Metabolites (nmol/24 hr; $n = 31$ Males and Females)

Biotin	Bisnorbiotin	Biotin sulfoxide
18–77	11–39	8–19

that are known to result from β -oxidation of fatty acids. The cellular site of this β -oxidation of biotin is uncertain. Nonenzymatic decarboxylation of the unstable β -keto-biotin and β -keto-bisnorbiotin leads to formation of bisnorbiotin methylketone and tetranorbiotin methylketone, which appear in urine. In the second pathway, the sulfur in the thiophene ring of biotin is oxidized, leading to the formation of biotin L-sulfoxide, biotin D-sulfoxide, and biotin sulfone. Combined oxidation of the ring sulfur and β -oxidation of the side chain lead to metabolites such as bisnorbiotin sulfone. In mammals, degradation of the biotin ring to release carbon dioxide and urea is quantitatively minor.

On a molar basis, biotin accounts for approximately half of the total avidin-binding substances in human serum and urine (Table 1). Biocytin, bisnorbiotin, bisnorbiotin methylketone, biotin sulfoxide, and biotin sulfone form most of the balance. Biotin metabolism is accelerated in some individuals by anticonvulsant therapy and during pregnancy, thereby increasing the ratio of biotin metabolites to biotin excreted in urine.

OCCURRENCE AND DIAGNOSIS OF BIOTIN DEFICIENCY

The fact that normal humans have a requirement for biotin has been clearly documented in two situations: prolonged consumption of raw egg white and parenteral nutrition without biotin supplementation in patients with short-gut syndrome and other causes of malabsorption (1). Deficiency of this member of the vitamin B group also has been clearly demonstrated in biotinidase deficiency (6).

The clinical findings and biochemical abnormalities in cases of biotin deficiency include dermatitis around body orifices, conjunctivitis, alopecia, ataxia, and developmental delay (1). The progression of clinical findings in adults, older children, and infants is similar. Typically, the symptoms appear gradually after weeks to several years of egg white feeding or parenteral nutrition. Thinning of hair progresses to loss of all hair, including eyebrows and lashes. A scaly (seborrheic), red (eczematous) skin rash was present in the majority of reports. In several reports, the rash was distributed around the eyes, nose, mouth, and perineal orifices. The appearance of the rash was similar to that of cutaneous candidiasis; *Candida albicans* could often be cultured from the lesions. These manifestations on skin, in conjunction with an unusual distribution of facial fat, have been dubbed "biotin deficiency facies." Depression, lethargy, hallucinations, and paresthesias of the extremities were prominent neurologic symptoms in the majority of adults, while infants showed hypotonia, lethargy, and developmental delay.

In cases severe enough to produce the classic cutaneous and behavioral manifestations of biotin deficiency, urinary excretion rates and plasma concentrations

of biotin are frankly decreased. Urinary excretion of the organic acids discussed in biochemistry section and shown in Figure 2 is frankly increased. The increase is typically 5- to 20-fold or more. However, such a severe degree of biotin deficiency has never been documented to occur spontaneously in a normal individual consuming a mixed general diet.

Of greater current interest and debate are the health consequences, if any, of marginal biotin deficiency. Concerns about the teratogenic effects have led to studies of biotin status during human gestation (44–48). These studies provide evidence that a marginal degree of deficiency develops in at least one-third of women during normal pregnancy. Although the degree of biotin deficiency is not severe enough to produce overt manifestations, the deficiency is severe enough to produce metabolic derangements. A similar marginal degree of biotin deficiency causes high rates of fetal malformations in some mammals (30,49,50). Moreover, data from a multivitamin supplementation study provide significant, albeit indirect, evidence that the marginal degree of deficiency that occurs spontaneously in normal human gestation is teratogenic (44).

Valid indicators of marginal biotin deficiency have been reported. Asymptomatic biotin shortage was induced in normal adults housed in a general clinical research center by egg white feeding. Decreased urinary excretion of biotin, increased urinary excretion of 3-hydroxyisovaleric acid, and decreased activity of propionyl-CoA carboxylase in lymphocytes from peripheral blood are early and sensitive indicators of biotin deficiency (30,31,51). On the basis of a study of only five subjects, 3-hydroxyisovaleric acid excretion in response to a leucine challenge appears to be an even more sensitive indicator of marginal biotin status (31). The plasma concentration of biotin and the urinary excretion of methylglycine, 3-hydroxypropionic acid, and 3-methylcitric acid do not appear to be good indicators of marginal biotin deficiency (52). In a biotin repletion study, the resumption of a mixed general diet produced a trend toward normalization of biotin status within 7 days. This was achieved when the supplement was started immediately at the time of resuming a normal diet. However, supplementation of biotin at 10 times the dietary reference intake (DRI) (300 $\mu\text{g}/\text{day}$) for 14 days reduced 3-hydroxyisovaleric acid excretion completely to normal in only about half of pregnant women who were marginally biotin deficient (47) suggesting a substantial depletion of total body biotin, a substantially increased biotin requirement, or both.

On the basis of decreased lymphocyte carboxylase activities and plasma biotin levels, Velazquez et al. (53) have reported that biotin deficiency occurs in children with severe protein-energy malnutrition. These investigators have speculated that the effects of biotin inadequacy may be responsible for part of the clinical syndrome of protein-energy malnutrition.

Long-term treatment with a variety of anticonvulsants appears to be associated with marginal biotin deficiency severe enough to interfere with amino acid metabolism (54–56). The mechanism may involve both accelerated biotin breakdown (56–58) and impairment of biotin absorption caused by the anticonvulsants (59).

Biotin deficiency has also been reported or inferred in several other circumstances including Leiner disease (60–62), sudden infant death syndrome (63,64), hemodialysis (65–69), gastrointestinal diseases and alcoholism (1), and brittle nails (70). Additional studies are needed to confirm or refute an etiologic link of these conditions to the vitamin's deficiency.

The mechanisms by which biotin deficiency produces specific signs and symptoms remain to be completely delineated. However, several studies have given new insights on this subject. The classic assumption for most water-soluble vitamins is that the clinical findings of deficiency result directly or indirectly from deficient activities of the vitamin-dependent enzymes. On the basis of human studies on deficiency of biotinidase and isolated pyruvate carboxylase, as well as animal experiments regarding biotin deficiency, it is hypothesized that the central nervous system effects of biotin deficiency (hypotonia, seizures, ataxia, and delayed development) are likely mediated through deficiency of brain pyruvate carboxylase and the attendant central nervous system lactic acidosis rather than by disturbances in brain fatty acid composition (71–73). Abnormalities in metabolism of fatty acids are likely important in the pathogenesis of the skin rash and hair loss (74).

Exciting new work has provided evidence for a potential role for biotin in gene expression. These findings will likely provide new insights into the pathogenesis of biotin deficiency (75,76). In 1995, Hymes and Wolf discovered that biotinidase can act as a biotinyl transferase; biocytin serves as the source of biotin, and histones are specifically biotinylated (6). Approximately 25% of total cellular biotinidase activity is located in the nucleus. Zemleni and coworkers have demonstrated that the abundance of biotinylated histones varies with the cell cycle, that these histones are increased approximately twofold compared with quiescent lymphocytes, and that these are debiotinylated enzymatically in a process that is at least partially catalyzed by biotinidase (77–79). These observations suggest that biotin plays a role in regulating DNA transcription and regulation.

Biotinylation of histones is emerging as an important histone modification. Recent studies from Hassan and Zemleni provide evidence that biotinylation likely interacts with other covalent modification of histones to suppress gene expression and gene transposition (80). Although the relative importance in biotinidase and holocarboxylase synthetase in the biotinylation and debiotinylation of histones has yet to be fully elucidated, Gravel and Narang have produced evidence that holocarboxylase synthetase is present in the nucleus in greater quantities than in the cytosol or the mitochondria and that holocarboxylase synthetase likely acts in the nucleus to catalyze the biotinylation of histones (81). Moreover, fibroblasts from patients with HCLS deficiency are severely deficient in histone biotinylation (82). Zemleni and coworkers have shown that biotinylation of lysine-12 in histone H4 (K12BioH4) causes gene repression and have proposed a novel role for HCS in sensing and regulating levels of biotin in eukaryotic cells (83). They have hypothesized that holocarboxylase synthetase senses biotin and that biotin regulates its own cellular uptake by participating in holocarboxylase synthetase-dependent chromatin

remodeling events at an SMVT promoter locus. Specifically, they hypothesize that nuclear translocation of HCS increases in response to biotin supplementation and then biotinylates histone H4 at SMVT promoters, silencing biotin transporter genes. This group has shown that nuclear translocation of HCS is a biotin-dependent process potentially involving tyrosine kinases, histone deacetylases, and histone methyltransferases. The nuclear translocation of holocarboxylase synthetase correlates with biotin concentrations in cell culture media and is inversely linked to SMVT expression. Moreover, biotin homeostasis by holocarboxylase synthetase-dependent chromatin remodeling at an SMVT promoter locus is disrupted in holocarboxylase synthetase knockdown cells.

Transposable elements such as retrotransposons containing long-terminal repeats constitute about half of the human genome, and the transposition events associated with these elements impair genome stability. Epigenetic mechanisms are important for transcriptional repression of retrotransposons, preventing transposition events, and abnormal regulation of genes. Zemleni and coworkers have provided evidence that the covalent binding of biotin to lysine-12 in histone H4 and lysine-9 in histone H2A mediated by holocarboxylase synthetase is an epigenetic mechanism to repress retrotransposon transcription in human and mouse cell lines and in primary cells from a human supplementation study. Abundance of biotinylation at those sites depended on biotin supply and on holocarboxylase synthetase activity and was inversely linked with the abundance of long terminal repeat transcripts. Knockdown of holocarboxylase synthetase in *Drosophila* enhanced retrotransposition. Depletion of biotinylation at those sites in biotin-deficient cells correlated with increased production of transposition events and decreased chromosomal stability.

Recently, controversy has arisen concerning the role of biotin as an *in vivo* covalent modifier of histones. Bailey and coworkers have reported that streptavidin binds to histones independently of biotinylation (84). To further investigate this phenomenon, 293T cells were grown in ^{14}C -biotin; in contrast to the ready detectability of ^{14}C -biotin in carboxylases, ^{14}C -biotin was undetectable in histones (i.e., represented no more than 0.03% of histones) (84). In a subsequent study, Healy and coworkers demonstrated that histone H2A is nonenzymatically biotinylated by biotinyl-5'-AMP and provided evidence that these enzymes promotes biotinylation of histone H2A by releasing biotinyl-5'-AMP, which then biotinylates lysines in histone H2A somewhat nonspecifically (85). Recently, this group has proposed that biotin is not a natural histone modifier at all. On the basis of studies that fail to find *in vivo* biotin incorporation into histones using ^3H -biotin uptake, Western blot analysis of histones, or mass spectrometry of affinity purified histone fragments, these investigators concluded that biotin is absent in native histones to a sensitivity of 1 part per 100,000 and that the regulatory impact on gene expression must occur through a mechanism other than histone modification (86). These conclusions are likely to generate a lively debate until definitive evidence is provided using mass spectrometric analysis of *in vivo* histones harvested at various phases of the cell cycle and at specific locations within particular histones.

Table 2 Adequate Intake for Biotin Consumption

Age	Amount ($\mu\text{g}/\text{day}$)
0–6 mo	5
7–12 mo	6
1–3 yr	8
4–8 yr	12
9–13 yr	20
14–18 yr	25
19– >70 yr	30
Pregnancy	30
Lactation	35

Note: Values for males and females in all age groups were combined because they do not differ.

Source: From Ref. 88.

INDICATIONS AND USAGE

In 1998, the United States Food and Nutrition Board of the National Academy of Sciences reviewed the recommendations for biotin intake (87). The committee concluded that the data were inadequate to justify setting an estimated average requirement. However, adequate intake (AI) was formulated (Table 2). The AI for infants was based on an empirical determination of the biotin content of human milk. Using the value for free biotin determined microbiologically ($6 \mu\text{g}/\text{L}$) and an average consumption of $0.78 \text{ L}/\text{day}$ by infants of age 0–6 months, an AI of $5 \mu\text{g}/\text{day}$ was calculated. The AI for lactating women has been increased by $5 \mu\text{g}/\text{day}$ to allow for the amount of biotin secreted in human milk. Using the AI for 0–6-month-old infants, the reference body weight ratio method was used to extrapolate AIs for other age groups (see Table 2).

TREATMENT OF BIOTIN DEFICIENCY

If biotin deficiency is confirmed, biotin supplementation should be undertaken and effectiveness should be documented. Doses between $100 \mu\text{g}$ and 1 mg are likely to be both effective and safe on the basis of studies supplementing biotin deficiency during pregnancy, chronic anticonvulsant therapy, and biotinidase deficiency.

TOXICITY

Daily doses of up to 200 mg orally and up to 20 mg intravenously have been given to treat biotin-responsive inborn errors of metabolism and acquired biotin deficiency. Toxicity has not been reported.

Bitter Orange

Steffany Haaz, K. Y. Williams, Kevin R. Fontaine, and David B. Allison

INTRODUCTION

Citrus aurantium (*C. aurantium*) is the Latin name for a plant commonly referred to as bitter orange, sour orange, Neroli, Chongcao, or Seville orange. It is a source of synephrine and several other biogenic amines, as well as other bioactive phytochemicals and has been used in dietary supplements for weight loss. In this entry, we discuss the available evidence pertaining to safety and efficacy of *C. aurantium* for weight loss, as examined in animal studies, clinical trials, and case reports.

GENERAL DESCRIPTION

Bitter orange is a member of the Rutaceae family, a hybrid between Pummelo, *Citrus grandis*, and Mandarin, *Citrus reticulata*. Native to Asia, various parts of the plant are used throughout the world for a variety of indications. Bitter orange and its components are commercially available in herbal weight loss supplements, ostensibly for their adrenergic agonistic properties (1), often in combination with other ingredients hypothesized to promote weight loss. Its constituent *p*-octopamine and synephrine alkaloids (SAs) are usually cited as the active ingredients in such products (2). With the banning of ephedra in the United States in 2004, bitter orange has been increasingly included in weight loss supplement formulations. Because of similarities in their constituents and possible mechanisms (both sources of natural alkaloids with sympathomimetic activity), concerns have been raised that bitter orange may carry risks similar to those hypothesized to exist for ephedra (3).

HISTORICAL USE

C. aurantium's origin is in China and appears in writing as far back as 300 BC. Its ancient use has also been documented in Japan and Rome (4). It is native to eastern Africa, Arabia, and Syria and is cultivated in various European, North American, and South American regions. The leaf was historically used as a tonic, laxative, or sedative in Mexico and South America and for insomnia, palpitations, or stomachaches by the European Basque people (5,6). The fruit and peel are also used for stomachaches, as well as high blood pressure (BP), spasm, and a variety of gastrointestinal conditions by both the Basque and practitioners of traditional Chinese medicine (7). While the practice arose in Ancient Egypt, neroli oil is still currently used for aromatherapy and bergamot, a subspecies of *C. aurantium*, is used for flavoring and aroma in Earl Grey teas (8). Modern uses for *C. aurantium* include digestive,

cardiovascular, neuromuscular, and antiseptic indications in countries such as China, Curacao, Haiti, India, Mexico, Trinidad, Turkey, and the United States (9). The most common current western use, however, is as a dietary supplement for weight loss.

POTENTIAL CONSTITUENTS

Some authors (10) state that *C. aurantium* contains *meta*-synephrine (*m*-synephrine, *m*-s), whereas others (11) state that it contains only *para*-synephrine (*p*-synephrine, *p*-s). However, research (I.A. Khan, oral communication, 2005) has shown that *C. aurantium* naturally contains *p*-synephrine and does not contain *m*-synephrine. Allison and colleagues reported that at least one over-the-counter (OTC) product purportedly containing SAs from *C. aurantium* contains both *p*-synephrine and *m*-synephrine (12), raising concerns about possible adulteration and mislabeling. There is also an *ortho* isomer of synephrine (*o*-synephrine), whose content in *C. aurantium* is unknown. *p*-, *m*-, and *o*-synephrine can each exist in D or L forms.

p-Synephrine, an undisputed component of *C. aurantium*, is typically referred to simply as synephrine (13). It is an α -adrenergic agonist (14) that also has some β -adrenergic properties (15). *p*-Synephrine occurs naturally in the human body in small quantities and might act as a neurotransmitter (16). Under the name oxedrine, it has been used since 1927 (17) in eyedrops. *p*-Synephrine is thought to be the ingredient in *C. aurantium* primarily responsible for weight loss. However, neither this nor whether *C. aurantium* actually produces weight loss in humans is firmly established.

m-Synephrine, often referred to as phenylephrine, is an isomer of *p*-synephrine. To the best of our knowledge, *m*-synephrine is not contained naturally in *C. aurantium*. *m*-Synephrine is also an α -adrenergic agonist that has some β -adrenergic agonist properties. It has been studied more extensively than *p*-synephrine and is one of the two most widely used OTC decongestants today (Fig. 1) (13). *p*-Synephrine and *m*-synephrine have similar structure to ephedrine, as well as other substances that have some effects on reducing food intake and/or body weight such as epinephrine and norepinephrine (Fig. 1), supporting the conjecture that, to the extent that function follows structure, *p*-synephrine and *m*-synephrine, may also reduce food intake and or body weight.

The α -adrenergic sympathomimetic amine, *p*-octopamine, is also present in *C. aurantium*, though possibly at inappreciable levels (2). Like both forms of synephrine, it is an α -adrenergic agonist with some

Figure 1 Chemical structures of (A) *p*-synephrine, (B) *m*-synephrine, (C) ephedrine, (D) epinephrine, and (E) norepinephrine.

β -adrenergic properties. It is used to treat hypertension and as a cardiostimulant (13) and has also been examined for its potential role in promoting weight loss (18).

Because of their similar properties and the overlap of their inclusion in supplements, we will refer to these substances collectively as synephrine alkaloids (SAs). SAs are used clinically as decongestants (1), during surgical procedures as a vasopressor (19), for acute treatment of priapism (20), and in ophthalmological examinations for pupil dilation (21). Products that contain *C. aurantium* or its derivatives, including OTC weight loss supplements, will be referred to as *C. aurantium* products (CAPs).

Regulatory oversight for dietary supplements is much less rigorous than for pharmaceuticals, and extensive evidence is not required prior to release of a product on the public market. While a phase of requirements for meeting good manufacturing practices is currently underway, this may help to explain why the quality and quantity of the evidence we have available to evaluate the safety and efficacy of *C. aurantium* is minimal.

POTENTIAL MECHANISMS

As sympathomimetic agents with both α - and β -adrenergic receptor agonist properties, SAs might increase energy expenditure and/or decrease food intake (22). In addition, there is some evidence that adrenergic agonists, including SAs, decrease gastric motility (23). Similar to compounds such as cholecystokinin and other gut peptides which both decrease gastric motility and food intake (24), one might conjecture that SAs may also decrease food intake via reducing gut motility. Activation of lipolysis is a known β -adrenergic activity (25) that may be fueled by these components of *C. aurantium*.

ANIMAL STUDIES

Weight Loss

SAs reduce food intake in rodents (26), and some studies indicate that SAs can reduce rodent body weight (13,26). SAs have also been shown to promote lipolysis in adipocytes through β -adrenergic stimulation (27) and to increase lipoprotein lipase activity in the parametrial fat pad of female hamsters (28). However, among monosodium glutamate-treated obese mice, SAs reduced weight gain but had no effect on body fat percent (29).

Toxicity and Mortality

Data suggest that *m*-synephrine (not present in bitter orange) may prolong life in rodents. A 2-year study by the National Toxicology Program (13) evaluated the effects of *m*-synephrine on spontaneous food intake of rats and mice. At 2 years, there were no significant differences in survival among mice or female rats. However, for male rats, there was a significant reduction in mortality rate, although there was increased mortality in the early phase of the study at the highest dose. It should be noted that too few deaths occurred during the 2-year trial to provide the degree of precision and power desired for a rigorous longevity study (30). Nonetheless, similar results have been reported for ephedrine, another sympathomimetic amine (31).

Arbo et al. (32) conducted a subchronic toxicity study in mice and the effects of *p*-synephrine and *C. aurantium* L. extract on oxidative stress biomarkers that are believed to be indicators of cell membrane injury (malondialdehyde) and (glutathione and the enzyme glutathione peroxidase) indicative of amphetamine-induced toxicity. The study evaluated adult male CF1 mice treated with 400, 2000, or 4000 mg/kg *C. aurantium* dried extract and *p*-synephrine 30 or 300 mg/kg over the course of 28 days. Results showed a reduction in glutathione in mice treated with *C. aurantium* 400 mg/kg and *p*-synephrine 30 and 300 mg/kg. Inhibition of glutathione peroxidase activity occurred within mice treated with *C. aurantium* 400 and 2000 mg/kg and *p*-synephrine 30 and 300 mg/kg; however, no change occurred within malondialdehyde levels. These two findings suggest the possibility of subchronic toxicity. No significant change in weight occurred in any of the groups, suggesting on the positive side a lack of severe toxicity, and on the negative side a lack of efficacy in producing weight loss.

With regard to adverse effects, a study (33) of male Sprague-Dawley rats reported what was believed to be evidence of cardiotoxicity when *C. aurantium* fruit extracts standardized to 4% and 6% SAs were administered. Increased mortality has been observed among CAPs-treated rats (33) as well as a strain of mice selected to be uniquely susceptible to the effects of adrenergic stimulation (34).

CLINICAL TRIALS

Weight Loss

Few clinical trials have examined the effects of CAPs alone or in combination with other ingredients on body weight and/or body composition (Table 1). It should be kept in mind that these trials are of short duration and the sample sizes are frequently quite small. Nonetheless, these trials suggest that body weight and/or fat loss may be enhanced by CAPs or SAs. The mechanisms involved are unclear but may be partially due to a suppressing effect of appetite and/or a moderate increase in resting energy expenditure.

Armstrong et al. (37) evaluated exercise and herbal preparation containing Ma Huang, bitter orange (5 mg SAs), and guarana over 6 weeks in a randomized, controlled trial. Compared with controls, the intervention group obtained significant reductions in fat mass and a nearly significant reduction in body mass index (kg/m^2).

Table 1 Summary of Clinical Weight Loss Trials

Reference	Treatment	Design	Sample size	Duration	Results	Comments
Colker et al. (10)	975 mg <i>Citrus aurantium</i> , +528 caffeine and 900 mg St. John's wort; placebo (with pill) and control (no pill)	Blinded parallel groups RCT	Supplement $n = 9$; placebo, $n = 7$; control group (no pills), $n = 4$	6 wk	Supplement group lost more fat (3.1 kg; $P < 0.05$) than other groups and increased RMR (2–3%)	<i>Citrus aurantium</i> may assist individuals in losing body fat, due to increased energy and reduced energy intake expenditure. No adverse events were reported
Kalman et al. (36)	Ephedrine and synephrine alkaloids (SAs) (5 mg twice daily) based product vs. placebo with exercise and diet	Prospective, randomized, double blind	30 overweight subjects; BMI > 27	8 wk	3.4 kg weight loss in experimental group vs. 2.05 kg in placebo ($P < 0.05$)	No adverse events; findings indicate apparent short-term safety and efficacy of ephedrine and synephrine-based compound
Armstrong et al. (37)	Exercise program with assignment to drug (Ma Huang, bitter orange, and guarana) or placebo. Bitter orange standardized for 5 mg synephrine	Randomized trial—unclear if study is blinded	Five overweight males/14 females	44 days	Supplement increased fat loss (2.5 kg; $P = 0.033$) more than placebo (0.5 kg)	Low statistical power, no marked side effects
Greenway et al. (38): Pilot 1	Two capsules containing pantothenic acid, 40 mg; green tea leaf extract, 200 mg; guarana extract, 550 mg; bitter orange, 150 mg; white willow bark extract, 50 mg; ginger root, 10 mg; proprietary charge thermoblend (L-tyrosine, L-carnitine, naringin), 375 mg	Prospective, randomized, double blind	Eight subjects (1:1 ratio) between supplement group and placebo group	8 wk	Supplement group gained more weight (1.04 ± 0.27 kg; $P < 0.04$) than placebo and increased RMR (but not at 8 wk)	CAP was not efficacious for weight loss
Greenway et al. (38): Pilot 2	<i>m</i> -Synephrine 20 mg	Prospective, randomized, double blind	Twenty subjects (1:1 ratio) between supplement group and placebo group	8 wk	Supplement group lost weight (0.8 ± 3.4 kg; <i>not significant</i>) in 8 wk, and increased RMR in 8 wk. No control group was used (Greenway, written communication, November 1, 2009)	<i>m</i> -Synephrine was not efficacious for weight loss

Abbreviations: BMI, body mass index; CAP, *Citrus aurantium* product; RCT, randomized, controlled trial; RMR, resting metabolic rate.

and fat percentage. No significant changes were noted in resting energy expenditure, blood chemistries, or dietary intake between the placebo and experimental groups.

In a double-blind, placebo-controlled, randomized trial, Colker et al. found that subjects receiving a combination of *C. aurantium*, caffeine, and St. John's wort, along with diet and exercise protocols, lost a statistically significant amount of body weight. Analysis comparing changes in this group with those in placebo or control groups on the same diet and exercise regimen did not show significant differences, though loss of fat mass was significantly greater in the experimental group (35). BP, heart rate, electrocardiographic, blood, and urine analyses were not significantly different between the groups.

Another randomized trial (36) of 30 overweight adults investigated the effects of supplementation, along with a cross-training exercise regimen and dietary education program compared with exercise and dietary education alone on body composition. Supplementation included ephedrine, SAs, caffeine, and calicine. Greater weight and fat loss occurred for the supplement group compared with the exercise–diet only group.

Overall, studies indicate a weight loss of 2.4–3.4 kg among participants using SAs, while placebo groups lost 0.94–2.05 kg, suggesting the plausibility of some weight loss benefit from SA supplementation, beyond diet and exercise alone. However, these studies do not separate

the effects of *C. aurantium* or SAs from other ingredients, particularly ephedrine and caffeine.

Metabolic Rate and Cardiovascular Effects

Several studies have evaluated the effects of acute administration of SAs on cardiovascular indicators. Kalman et al. (39) tested a product containing 335 mg Ma Huang standardized for 20 mg ephedrine alkaloids, 910 mg guarana standardized for 200 mg caffeine, and 85 mg bitter orange standardized for 5 mg SAs per two capsules. Twenty-seven overweight adults were randomized to treatment or placebo for 14 days. BP, heart rate, electrocardiogram, and Doppler echocardiograms were evaluated before and after treatment. Ingestion of this commercial weight loss supplement did not produce any detectable cardiovascular side effects.

Penzak et al. (10) examined cardiovascular outcomes in 12 normotensive individuals who were administered 8 oz of Seville orange juice (containing 13–14 mg SAs) and water in a crossover fashion, followed by a repeat ingestion 8 hours later. No changes in cardiovascular indices (BP, maximal arterial pressure, and heart rate) were detected.

Thomas et al. (40) evaluated the cardiovascular effects of 10 mg oral SAs in healthy volunteers over a 4-hour period on impedance cardiography and forearm plethysmography. Elevation in total peripheral resistance was observed 30–60 minutes after dosing, although other hemodynamic indexes were not affected.

Hemodynamic effects were observed in a crossover design, placebo-controlled study (41) with the administration of Xenadrine, a CAP that contains a variety of other potentially bioactive substances, including green tea extract, cocoa extract, yerba mate, ginger root, grape seed extract, and others. However, these increases in heart rate, and systolic and diastolic BP were not observed with administration of Advantra Z, which contains *C. aurantium* alone, even at an eightfold higher dose.

Haller et al. (42) evaluated a dietary supplement [Ripped Fuel Extreme Cut, containing synephrine from *C. aurantium* (presumably *p*-synephrine) and caffeine] in 10 healthy adults (three women) aged 20–31 years. Each subject was given one dose of the dietary supplement under three conditions: (i) resting conditions (without placebo); (ii) moderately intense exercise; and (iii) placebo plus moderately intense exercise in a three-arm, randomized, crossover study. Greater postexercise diastolic BP was seen with the dietary supplement plus exercise than with placebo plus exercise. There were no obvious supplement effects on postexercise HR, systolic BP, or body temperature.

Bui et al. (43) reported the effect on BP (systolic and diastolic) and heart rate over 6 hours after one dose of a CAP (Nature's Way Bitter Orange) on 15 young, healthy adults in this prospective, randomized, double-blind, placebo-controlled, crossover study. Systolic and diastolic BP increased significantly within the 1–5 hours time period in comparison with the placebo group with the peak being 7.3 ± 4.6 mm Hg, while the 4–5 hours time period increase was 2.6 ± 3.8 mm Hg after consumption in comparison with the placebo group with the peak being 4.2 ± 4.5 beats/minute, while

heart rate was significantly elevated 2–5 hours after ingestion.

In one study of obese adults, increases in resting metabolic rate (RMR) were observed with *C. aurantium*, both alone and with food, beyond the thermic effect of food (TEF) alone (44). (RMR is a measure of the energy required to maintain basic physiological function while the body is at rest.) However, another recent investigation (45) found that the thermic response to CAPs increased in women only, who had lower TEF than men at baseline. After the intervention, TEF did not differ by gender. BP and pulse rate were not affected, but epinephrine secretion increased. In normal weight adults, an increase in RMR was also found when the extract was taken with a meal (46). No adverse changes in pulse rate or BP were reported.

Finally, the effects of two dietary supplement formulas on RMR and other metabolic indicators were evaluated (47). When compared with placebo, Formula A (containing ephedra, guarana, green tea, yohimbe, and quercetin) and Formula B (containing *C. aurantium*, jing jie, fang feng, guarana, green tea, yohimbe, and quercetin) resulted in increased total RMR, decreased respiratory exchange ratio toward fat burning, and increased body core temperature. Heart rate and RMR increased at each 15-minute interval with Formula A only. BP increased with both, but to a greater extent with Formula A.

CASE REPORTS OF ADVERSE EVENTS

Nykamp et al. (48) describe a case of acute lateral-wall myocardial infarction co-occurring with consumption of CAPs in a 55-year-old woman with undetected coronary vascular disease. She reported taking a multicomponent dietary weight loss supplement containing 300 mg of bitter orange over the preceding year.

A Consumer Reports article (49) describes a 21-year-old woman who took ephedra-free *Xenadrine EFX* (which contains *C. aurantium*). After 3 weeks on the supplement, she suffered a seizure. Her neurologist believes the bitter orange in the supplement was the most likely the cause, though the basis for this conclusion is unknown.

Nasir et al. (50) described exercise-induced syncope in a healthy 22-year-old woman that occurred 1 hour after a second dose of *Xenadrine EFX*, a weight loss supplement that contains, among other compounds, ephedrine and synephrine. The electrocardiography revealed prolongation of the QT interval, which resolved in 24 hours.

Bouchard et al. (51) report a case of a 38-year-old male patient with ischemic stroke that occurred after taking a CAP for 1 week. The patient reportedly had no relevant medical history or major atherosclerotic risk factors and took no other medications.

Gray and Woolf (52) reported a case of CAPs use by an adolescent with anorexia nervosa and raised concerns that the SAs may have masked bradycardia and hypotension while exacerbating her weight loss. Firenzuoli et al. (53) report a case of a 52-year-old woman that had an allergic reaction after taking a CAPs product.

Sultan et al. (54) reported a case of a 52-year-old woman with ischemic colitis that occurred 1 week after consumption of a CAP (Natural Max Skinny Fast, containing bitter orange). She reported no known drug

Table 2 Summary of Effects, Safety, and Efficacy of *Citrus aurantium*

Physiological effects	Effects on weight	Effects on body composition	Safety
Variable changes in BP in animals; generally stable BP, heart rate, pulse rate, blood and urine measures in humans; inconsistent changes to resting metabolic rate	Weight loss documented in rodents; weakly supported in humans, as studies used multiple supplements or did not find significant difference from controls	Limited support for loss of fat mass in human studies, noting a trend or using multiple supplements; for animals, some increased lipase activity	Inconsistent mortality data in rodents; some evidence of elevated BP. Results not consistent from study to study, but this may be a function of small sample sizes used in most studies. Several case reports of serious adverse events

allergies and took no other medications. Symptoms resolved over 24–48 hours with conservative management after the supplement was discontinued.

Health Canada reported that from January 1, 1998, to February 28, 2004, it received 16 reports in which products containing bitter orange or synephrine were suspected of being associated with cardiovascular events, including tachycardia, cardiac arrest, ventricular fibrillation, transient collapse, and blackout. All cases were considered serious (55).

Adverse events from CAPs are currently fairly rare in scientific literature. As CAPs are used more widely in place of ephedrine-containing products, any potentially harmful effects may be clarified over time.

DISCUSSION

The Safety of CAPs

Some have hailed the potential therapeutic value of CAPs (1), while others have warned about possible safety concerns (33). The safety concerns pertain primarily to adverse cardiovascular and cerebrovascular effects. Information on the safety of CAPs comes from the three sources described above: animal studies, clinical trials, and case reports. To date, no large epidemiologic (case control or cohort) studies have evaluated the safety of CAPs.

Of course, one cannot extrapolate the safety of CAPs from short-term studies used for one indication (e.g., several days for relief of nasal congestion among the general population) to long-term studies use for another indication (e.g., several months or years for weight loss among obese individuals). Although substantial safety-related data exist for CAPs (13,56), there is no published human weight loss trial of CAPs with more than 20 participants or for a duration of more than 7 weeks.

It is important to note that the majority of studies evaluating the safety of CAPs are performed with normotensive subjects. However, because hypertension is a common comorbidity associated with overweight/obesity, studies that evaluate the effects of CAPs on BP should also be conducted with obese hypertensive adults.

While *C. aurantium* extracts have been used in a variety of cultures for thousands of years, they have not been traditionally utilized for long periods of time, or specifically for weight loss (1). As such, there is little, if any, basis for making definitive statements about the intermediate or long-term safety/risk of CAPs used for weight loss. Table 2 summarizes the physiological effects, safety, and weight loss efficacy of *C. aurantium*.

DOSE CONSIDERATIONS

Given the dearth of weight loss trials, the optimal dose (if one exists) of *C. aurantium* or its SA constituents for weight loss is unknown. Table 3 highlights some relevant dosage information. Although generalizing across species and compounds is difficult and can only provide a limited basis for conjecture, the following comparisons with ephedrine can be made. We analyzed data (12) in which ephedrine or SAs was given to mice. Regression of weight and food intake on dose of ephedrine or SAs yielded slopes (in absolute value) that were approximately four to six times greater for ephedrine than for SAs. Based on linear projections, it would take four to six times the dose of SAs (in these mice) to achieve equivalent reduction in intake and body weight as for ephedrine. In human studies of ephedrine, doses of about 50 mg per day begin to be effective (57). Although an extrapolation, this might suggest a useful clinical dose for SAs as high as 240–360 mg

Table 3 Dosage Information on *Citrus aurantium* or Synephrine Alkaloids (SAs)

Dose	
5–14 mg/day	<i>Citrus aurantium</i> extract with SAs has been used (34–36) and no serious adverse events were reported. These doses <i>purportedly</i> showed efficacy, but products tested included substances beyond <i>C. aurantium</i> , notably ephedrine which we know to be effective for weight loss. We believe that these doses of SAs are very unlikely to be effective when used without ephedrine
32 mg/day	The nasal decongestant Endal (60) contains 20 mg of <i>m-s</i> per tablet and two tablets per dose twice per day are recommended
120 mg/day	Via <i>C. aurantium</i> extract, SAs are marketed in over-the-counter (OTC) products for weight loss. In products, such as Nutres Lipo 6 (61), the directions suggest that for “extreme fat loss” a recommended dosage is two capsules three times per day. The SA content per capsule is 20 mg; this provided a maximal recommended dose of 120 mg/day
300 mg/day	According to <i>Clarke’s Analysis of Drugs and Poisons</i> (62), oxedrine (<i>p</i> -synephrine) is used clinically at ~300 mg/day
1000 mg/day	Minimum adult lethal dose of <i>m-s</i> (63)

per day. From a safety point of view, SAs (per equal weight) have lower potential to raise BP than ephedrine; however, nearly all commercial preparations of SAs also contain caffeine, which might compound any cardiovascular effects. In the absence of caffeine, human studies suggest that 15–30 times the dose of SAs are required to elevate BP to the same degree as ephedrine (58,59). This suggests that such high doses might be well tolerated, but clearly more data are needed, particularly regarding potential synergistic effects of CAPs components.

SAs appear to be readily absorbed after oral administration (63). About 80% of oral doses are excreted in the urine within 24 hours. After single oral doses, peak plasma concentrations are typically reached in 1–2 hours. Plasma half-life is ~2–3 hours. Sympathomimetic drugs for weight loss are typically given TID before meals (64) reducing the evening dose if sleep problems arise.

CONTRAINDICATIONS

Topical application (as with aromatherapy or antifungal uses) of CAPs may result in photosensitivity for fair-skinned individuals (65) (possibly due to photosensitizing furanocoumarins that occur in the rinds of certain citrus species, especially immature fruits). Although rare, this has also occurred after oral ingestion. To reduce this risk, exposure to ultraviolet light can be minimized. Caution is recommended for use in children, as it may conceivably produce toxic effects (66). Some sources advise that CAPs should be avoided by women who are pregnant or breast-feeding (7,67), while others claim that CAPs can be used safely during pregnancy (66). While effects on BP are unclear, those with hypertension, tachyarrhythmia, or narrow-angled glaucoma may consider refraining from use of CAPs until further evidence confirms their safety (67). CAPs could also possibly exacerbate symptoms for those with stomach or intestinal ulcers (68).

DRUG INTERACTIONS

Because CAPs may increase stomach acid, they could potentially reduce the efficacy of acid-lowering drugs, such as antacids and ulcer medications (69). Although a speculative precaution, those taking medications containing SAs, including some cold medications and monoamine oxidase inhibitors (MAOIs), should consider the combined dose of these products with the SAs present in CAPs formulations and possible multiplicative effects (68,69). It has been suggested that CAPs could interfere with the activity of drugs that are metabolized by the liver enzyme cytochrome P450-3A, CYP3A (70,71). A recent comment in *Experimental Biology and Medicine* noted that some research on drug effects have utilized parts of the plant or methods of administration that may not be applicable to oral consumption of currently marketed dietary supplements (72).

FUTURE RESEARCH

The safety and efficacy of CAPs and SAs for weight loss are not well established. While existing literature

demonstrates plausibility for reducing weight, previous trials were not designed to rigorously evaluate safety and efficacy. Doing so will require better-designed randomized clinical trials with large sample sizes, reliable well-established outcome measures, and active surveillance of side effects and adverse events. To better understand the effects of CAPs or SAs specifically, studies will need to test these components without combining them with other ingredients postulated to have antiobesity effects. It would also be worthwhile to examine differences between the types of synephrine-containing compounds that are derived from various sources and how this influences the consistency and potency of supplements.

Black Cohosh

Daniel S. Fabricant, Elizabeth C. Krause, and Norman R. Farnsworth

INTRODUCTION

Black cohosh is a native eastern North American plant that was used as traditional medicine by Native Americans. Extracts of the roots and rhizomes were used for analgesic, sedative, and anti-inflammatory properties. More recently, root and rhizome black cohosh preparations have had a rich clinical history, spanning almost 60 years of study. These studies have primarily focused on relieving climacteric symptoms associated with menopause as a possible alternative to classical hormone or estrogen replacement therapy.

BACKGROUND

The common name for black cohosh [*Actaea racemosa* L. syn., *Cimicifuga racemosa* (L.) Nutt. (Ranunculaceae, Buttercup Family)] originated with North American Indians. The term cohosh is thought to be an Algonquian word meaning "rough," with reference to the texture of the thick, knotted roots and underground stems (rhizomes). A New World plant used by Native Americans, it was most abundant in the Ohio River Valley, but it could also be found from Maine to Wisconsin, south along the Allegheny Mountains to Georgia, and west to Missouri.

Various common names have been used to refer to black cohosh, including black snakeroot, bugbane, rattleroot, squawroot, and macrotys. It is a member of the Ranunculaceae or Buttercup family, which includes other medicinal plants such as aconite, goldenseal, and pulsatilla. It has been known by the scientific name *C. racemosa* and recently has been reassigned to *A. racemosa*. The generic name *Cimicifuga* derives from the Latin *cimex* (a kind of bug) and *fugare* (to put to flight), which is perhaps indicative of the use of some strongly smelling close relatives to repel insects. The specific epithet *racemosa* refers to the flowering stalk, termed a raceme. The name rattleroot is indicative of the rattling sound made by the dry seeds in their pods. This plant prefers the shade of rich open hardwood forests, but it will tolerate some sunny spots.

Black cohosh has been used clinically for relief of climacteric symptoms for more than 60 years, and its popularity in the United States as a botanical dietary supplement has increased due to the recently recognized potential risks associated with classical estrogen replacement therapy or hormone replacement therapy (1,2). The part of the black cohosh plant used in medicinal preparations is the root and rhizome. It was officially recognized in the

United States Pharmacopeia (USP) from the first edition in 1820 to 1936 and in the National Formulary from 1936 to 1950. The eclectic physicians used a preparation of black cohosh called macrotys. It was considered one of the best-known, specific medicines for heavy, tensive, and aching pains as it was noted to have a direct influence on the female reproductive organs.

While the mechanism of action has not been completely elucidated, recent literature suggests that alleviation of climacteric symptoms is mediated through neurotransmitter regulation and not through classical estrogen receptor (ER) endocrine pathways (3,4).

CHEMISTRY

More than 60 triterpene glycosides, most with a 9,19 cycloartane skeleton, and unique to *Actaea* spp., have been reported from the roots and rhizomes of *A. racemosa* (5,6). The compound 23-*epi*-26-deoxyactein (formerly 27-deoxyactein) is the constituent usually selected for standardization of commercial products based on its abundance in the roots and rhizomes (7–12). The pharmacokinetics of 23-*epi*-26-deoxyactein in serum and urine has recently been reported (13). While triterpenes are structurally similar to steroids and possess a broad range of biological activity (14–17), no significant ligand binding affinity was found toward ER- β in the evaluation of 23-*epi*-26-deoxyactein, cimicifugoside F and cimicifugoside, and their respective aglycones (18). This, coupled with the lack of demonstrated estrogenic activity in *A. racemosa* extracts, has called into question the notion that black cohosh acts through direct ER binding by the triterpenes, as has been hypothesized (19–23).

In addition to the triterpene saponins, the roots and rhizomes of black cohosh also contain a number of aromatic acids/polyphenols that possess a wide array of biological activities (5,24–26). Caffeic acid, which is found widely across all species of flowering plants, has shown pregnant mare antigonadotropin activity (27–29), rat uterine antispasmodic activity (30), and smooth muscle relaxant/antispasmodic activity in rats (31) and guinea pig ileum (32). Ferulic acid, also more or less ubiquitous among flowering plants, has demonstrated luteinizing hormone (LH) release inhibition (33), follicle-stimulating hormone (FSH) release stimulation (33), antiestrogenic activity (34), prolactin stimulation in cows (35) and inhibition in rats (33), and uterine relaxant/antispasmodic activity in rats (36). Fukinolic acid produced an estrogenic effect on MCF-7 cells with reference to estradiol

(37). A more recent study refuted this effect and demonstrated a lack of estrogenic effect for 10 other phenolic esters, many of which are unique to *Actaea* spp. (caffeoylglycolic acid; 2-caffeoylpiscidic acid (cimicifugic acid D); 3,4-dihydroxyphenacyl caffeate (petasiphenone); 3,4-dihydroxyphenyl-2-oxopropyl isoferulate (cimiciphenol); 3,4-dihydroxyphenacyl isoferulate (cimiciphenone); cimicifugic acids A, B, E, F; and fukiic acid) from black cohosh (38).

Studies on the phenolic acid constituents of black cohosh have shown antioxidant activity (24,39) that may correlate with or prove useful in the determination of the mechanism of action of black cohosh. In addition, a number of plant sterols and fatty acids, generally regarded as ubiquitous in the plant kingdom, are contained in the roots and rhizomes for which the biological activities probably do not relate to the mechanism of action of black cohosh (5). In the past 5 years, novel guanidine alkaloids have been isolated from *A. racemosa* underground parts (40,41). New phytochemical methodology called pH zone refinement gradient centrifugal partitioning chromatography coupled with a sensitive liquid chromatography–mass spectral dereplication method led to the identification of *N*-(omega)-methylserotonin as a potential active principle with serotonergic properties (41). Alkaloids have also been reported from other *Actaea* spp. roots and rhizomes (42,43).

There has been some debate over the occurrence of the weakly estrogenic compound formononetin in the plant (44–49). Although there has been at least one report of its occurrence in *A. racemosa* (46), prior studies using plant material collected from different sites in the Eastern United States at different times of the year failed to find formononetin (47,48). More recent studies on both commercial black cohosh products and wild-crafted material, incorporating both high-performance liquid chromatography with mass spectral and photodiode array detection, confirmed the prior findings of no detectable formononetin in black cohosh (8,49).

BOTANICAL DESCRIPTION

A. racemosa syn. *C. racemosa* is an erect, smooth-stemmed perennial 1–2.5 m in height. Large compound leaves are alternately arranged and triternate on short clasping petioles. Basal leaf petioles are grooved in young specimens. This shallow, narrow sulcus in *A. racemosa* disappears as the petiole enlarges, whereas it remains present throughout the life of the two related eastern North American species, *A. cordifolia* DC syn. *C. rubifolia* Kearney and *A. podocarpa* DC syn. *C. americana* Michx (50). Terminal leaflets of *A. racemosa* are acute and glabrous with sharp serrated margins, often trilobate, occasionally bilobed. Fruits are ovoid follicles occurring sessile on the pedicel. The flowering portion, the raceme, is a long wand-like structure with showy white flowers. The flowers possess numerous characteristic stamen and slender filaments with distinctive white anthers (51). The roots and rhizomes are branched and knotted structures with a dark brown exterior and are internally white and mealy or brown and waxy. The upper rhizome surface has several buds and numerous large stem bases terminated frequently by deep, cup-shaped, radiating scars, each of which show a radiate

structure or less frequently fibrous strands. Lower and lateral surfaces exhibit numerous root scars and a few short roots. The fracture is horny, the odor slight, and the taste bitter and acrid (52).

EFFECTS ON CLIMACTERIC SYMPTOMS RELATED TO MENOPAUSE

With a history of clinical study spanning almost 60 years, mainly in Europe (53), black cohosh is one of the more popular alternatives to hormone replacement therapy. Most of the clinical research over this span has been performed on the product known as Remifemin[®], whose formula has changed over the years. However, a number of other commercial formulations are also available. In 2007, black cohosh was the 50th best-selling dietary supplement in the United States with sales of approximately \$52 million (USD), according to the Nutrition Business Journal (54).

Black cohosh clinical study outcomes have been evaluated using a variety of tools, including self- or physician assessments of symptom scores and physiological parameters. Typical measurements include psychological, neurovegetative, somatic, and physiological markers of menopause or relief from the climacteric symptoms of menopause. As in all clinical trials, study design is vital, so studies that are adequately powered, incorporate proper controls, and are designed to address confounders relevant to climacteric symptoms such as the placebo effect and botanical product quality should be given more weight than studies that are not as well designed (55–59).

Placebo effects in menopausal trials are generally large (60) and reflect underlying fluctuations of symptoms. Therefore, any well-designed study must adjust the appropriate variables (i.e., study duration, number of subjects (*n*), and/or dosage) to account for such an effect. In the evidence-based medicine model, the gold standard in terms of efficacy involves randomized, controlled trials (RCTs). Many RCTs on black cohosh exist. When high-quality studies are combined, more than 3000 subjects have been randomized, with the more recent studies adding layers of design sophistication. For example, double-blind, multicenter, placebo-controlled trials that provide details regarding clinical material specifications are becoming more prevalent (55–60).

A recent phase III, double-blind, randomized, placebo-controlled crossover trial of the effectiveness of black cohosh for the management of hot flashes was conducted over two 4-week periods (one capsule, 20 mg bid) (61). The study used a daily hot flash diary and found that subjects receiving the black cohosh material reported a mean 20% decrease in hot flash score (comparing the fourth treatment week to the baseline week) versus a 27% decrease for patients on placebo ($P = 0.53$), mean hot flash frequency was reduced 17% in the black cohosh group and 26% on placebo ($P = 0.36$). Thus, the authors concluded that the study did not provide any evidence that black cohosh reduced hot flashes more than the placebo. Critics of the study point to the short duration and low dose as potential confounders of the results.

The Herbal Alternatives for Menopause trial or HALT trial compared the efficacy of 160 mg daily black

cohosh against several other interventions (200 mg daily multibotanical with black cohosh and nine other ingredients; 200 mg daily multibotanical plus dietary soy counseling; 0.625 mg daily conjugated equine estrogen with or without 2.5 mg medroxyprogesterone acetate daily; and placebo) in 351 menopausal and postmenopausal women of ages 45–55 years with two or more vasomotor symptoms per day. Results did not suggest efficacy for any of the herbal interventions when compared with placebo at any time point over the 1-year course of the study (62).

The Jacobson study (63), spanning only 60 days of treatment, suggests that the short study duration may have limited the findings (60). In addition, all the study participants had a history of breast cancer. The authors reported that the median number of hot flashes decreased 27% in both the placebo and black cohosh groups. No significant differences were observed between groups. Thus, black cohosh, on the basis of this study, was no more effective than placebo in the treatment of hot flashes. The source and formulation of the extract used in this study was not specified. A more recent open-label study that treated breast cancer survivors with either Tamoxifen[®] or a combination of BNO 1055, a proprietary black cohosh extract, with Tamoxifen suggested a reduction in the number and severity of hot flashes in the combination treatment group (64).

In another randomized, double-blind, placebo-controlled study that lasted 12 weeks, black cohosh was compared with standard conjugated estrogen (CE) therapy (0.625 mg/daily). Patients' physical and psychological symptoms were measured every 4 weeks. The end result of the study was that the patients treated with black cohosh had significantly lower index scores on both the Kupperman menopausal (KM) and the Hamilton menopausal (HAM-A) scales compared with placebo, indicating a decrease in severity and frequency of hot flashes. In addition, this study showed an increase in the number of estrogenized cells in the vaginal epithelium in the black cohosh treatment arm, which could indicate an estrogenic action in this tissue (65).

In 2003, a similar study compared effects of two different preparations of BNO 1055 extract and CE therapy on climacteric symptoms and serum markers of bone metabolism (66). The study outcomes were evaluated using patient self-assessment (diary and menopause rating scale), CrossLaps (to measure bone resorption), bone specific alkaline phosphatase (marker of bone formation), and endometrial thickness (measured by ultrasound). Both BNO 1055 extracts were equipotent to CE therapy and significantly greater than placebo at reducing climacteric complaints. In addition, the study showed that both BNO 1055 preparations had beneficial effects on bone metabolism in serum. Specifically, an increase in bone-specific alkaline phosphatase and no reduction in bone resorption were noted indicating an increase in bone turnover formation. No change in endometrial thickness was observed in either BNO 1055 treatment groups, but it was significantly increased with CE therapy. An increase in superficial vaginal cells was observed in the CE and both BNO 1055 treatment groups. The authors of the study hypothesized that the activity of both BNO 1055 preparations was similar to the effects of selective estrogen receptor modulating (SERM), that is, Raloxifene[®] therapy on

bone and neurovegetative climacteric symptoms, without any uterotrophic effects (66).

A recent high-quality, double-blind, randomized study evaluated the effects of two dosages (low, 39 mg; high, 127 mg) of a Remifemin extract on menopausal symptoms. Effectiveness was measured using the KM index, self-assessment depression scale (SDS), clinical global impression scale (CGI), serum levels of LH and FSH, sex hormone-binding globulin, prolactin, 17- β -estradiol, and vaginal cytology. Reductions in the KM and SDS indices were significant. Global efficacy (CGI) was scored at good to very good in 80% (low dosage) and 90% (high dosage) of the patients in the treatment groups (67). No effect on serum hormone levels or vaginal cytology was shown, prompting the authors of the study to suggest that black cohosh does not have a direct estrogenic effect on the serum hormone levels or vaginal epithelium (68). Two recent open-label studies using unspecified types of extracts reported reduced KM index scores. One study reported a significant reduction in 1 month (69), while the other, which also used the HAM-A scale, recorded a 90% improvement in climacteric symptoms in menopausal women after 3 months of black cohosh administration (70).

Chung and colleagues (71) examined a combination of black cohosh and St. John's wort (Gynoplus[®]) in a multicenter RCT in 89 peri- or postmenopausal women with climacteric symptoms. Subjects were treated for 12 weeks with either the Gynoplus extract or placebo. In addition to climacteric complaints, investigators also examined effects on vaginal atrophy, serum hormone levels (FSH, LH), and lipid profiles [total cholesterol, high-density lipoprotein (HDL) cholesterol, low-density lipoprotein cholesterol, and triglyceride]. Significant improvements in climacteric symptoms and hot flashes, as well as an increase in HDL, were observed in the Gynoplus group by 4 weeks and maintained after 12 weeks, but there was no significant impact on vaginal atrophy.

In a 12-month, randomized, four-arm, double-blind clinical trial of standardized black cohosh, red clover, placebo, and 0.625 mg conjugated equine estrogens plus 2.5 mg medroxyprogesterone acetate (conjugated equine estrogens (CEE) and medroxyprogesterone acetate (MPA); $n = 89$), black cohosh did not significantly reduce the frequency of vasomotor symptoms as compared with placebo. The primary outcome measures were reduction in vasomotor symptoms (hot flashes and night sweats) by black cohosh and red clover compared with placebo; secondary outcomes included safety evaluation, reduction in somatic symptoms, relief of sexual dysfunction, and overall improvement in quality of life. Reductions in number of vasomotor symptoms after a 12-month intervention were as follows: black cohosh (34%), red clover (57%), placebo (63%), and CEE/MPA (94%), with only CEE/MPA differing significantly from placebo. Secondary measures indicated that both botanicals were safe as administered. In general, there were no improvements in other menopausal symptoms (72).

A 12-week trial investigating the effects of black cohosh on menopause-related anxiety disorder found no statistically significant anxiolytic effect of black cohosh versus placebo. However, small sample size, choice of black cohosh preparation, and dosage used may have

contributed to the negative results according to the study's authors (73).

More details of the human studies discussed here, as well as others, are presented in Table 1.

BIOCHEMISTRY AND FUNCTIONS

Despite the extensive clinical research, the mechanism of action of black cohosh on menopausal and other symptoms remains unclear, which is consistent with the varied results from clinical trials. A majority of the older literature suggest a direct estrogenic effect. More recent hypotheses have proposed an effect on the limbic system (hypothalamus) or an effect on the neurotransmitters involved in regulation of this system as being responsible for the activity of black cohosh. Data fall into the following categories.

Estrogen Receptor Competitive Binding

The first report of ER-binding activity of black cohosh indicated this as a possible mechanism of action (74). Additional studies were carried out to substantiate this purported endocrine activity (75,76). However, a factor frequently overlooked regarding black cohosh receptor binding studies is the lipophilic nature of the extracts tested. Chemically, lipophilic extracts and fractions that display ER-binding activity are significantly different from the typical hydroalcoholic extracts used to make products for human consumption. A lipophilic extract of the plant showed relatively weak (35 $\mu\text{g/mL}$) ER binding on rat uteri (75). Another study also confirmed the ER-binding activity of an unspecified lipophilic subfraction on ovariectomized (ovx) rat uterine cells, with no binding activity seen with a hydroalcoholic extract (76).

Recent reports have contradicted the ER-binding affinity of black cohosh extracts (4,20,22,77,78). A root extract tested in an in vitro competitive cytosolic ER (from livers of ovx rat) binding assay with diethylstilbesterol (50), an inhibitor of estrogen binding, showed a significant inhibition of estradiol binding in the presence of diethylstilbesterol (77). However, no binding was demonstrated for the black cohosh extract. A hydroalcoholic *A. racemosa* rhizome extract (50% aqueous ethanol) was assayed for ER binding in intact human breast cancer cell lines MCF-7 and T-47-D. Again no binding affinity was shown for the black cohosh extract. However, binding activity was evident for other hydroalcoholic plant extracts, such as red clover (78). In another study, a high concentration (200 $\mu\text{g/mL}$) methanol extract of black cohosh displayed no binding affinity for recombinant diluted ER- α and ER- β (20). A study using BNO 1055 showed contrasting results (79). The extract displayed dose-dependent competition with radio-labeled estradiol in both a porcine and human endometrial cytosolic ER ligand-binding assay system. However, the extract did not displace human recombinant ER- α and ER- β . These contradictory findings prompted the authors to suggest that their product contains estrogenic compounds that have binding affinity for a putative ER- γ . The absence of a direct estrogenic effect was again confirmed in a human study (21). Postmenopausal women took black cohosh extract for 12 weeks followed by a 12-week washout. Black cohosh demonstrated no effect on

estrogenic markers in serum and no effect on pS2 or cellular morphology in nipple aspirate fluid (21).

Receptor Expression

As with the receptor-binding assays, the nature of the extract or fraction is a decisive factor in the expression of ERs. A lipophilic and hydrophilic black cohosh extract was studied for luciferase expression in a MCF-7 α - and β -ER expressing subclone (80). The lipophilic extract at 35 $\mu\text{g/mL}$ activated transcription of the estrogen-regulated genes, while the hydrophilic extract showed no activity. A recent study measuring an extract at a low concentration (4.75 $\mu\text{g/L}$) increased ER levels in human MCF-7 cells as did estradiol (81). An unspecified black cohosh extract tested in a transient gene expression assay using HeLa cells co-transfected with an estrogen-dependent reporter plasmid in the presence of human ER- α or ER- β cDNA failed to show transactivation of the gene (82).

Plasma Hormone Levels

The effect of black cohosh on serum concentrations of FSH and LH has been studied extensively. Crude alcoholic extracts suppressed plasma LH with no effect on FSH in ovx rats (75,77). Further fractionation of the crude extract resulted in activity of the lipophilic fraction while the hydrophilic fractions were devoid of this activity (74). A later study in rats using lipophilic and hydrophilic extracts at high doses (140 and 216 mg/rat, IP) resulted in LH suppression with a single injection administration of the lipophilic but not the hydrophilic extract (75). Another study reported LH suppression in ovx rats with an unspecified dose of black cohosh extract (83). A recent study compared the effect of BNO 1055 with that of estradiol on LH levels (79). Extract administered subcutaneously at a dosage of 60 mg/day for 7 days was reported to reduce LH levels in the treated animals. However, another study reported no estrogen agonistic effects on FSH, LH, or prolactin levels in ovx rats using the 7,12-Dimethylbenz(a)anthracene model following 7 weeks of daily administration of a 40% isopropanolic extract of the plant (Remifemin) (84).

Hormonal Secretion

The effect of black cohosh on prolactin secretion in pituitary cell cultures was measured using an unspecified extract (85). Basal and Thyrotropin-releasing hormone (TRH)-stimulated prolactin levels were significantly reduced at doses of 10 and 100 $\mu\text{g/mL}$. This effect was reversed by the addition of haloperidol (D₂-antagonist) to the cell cultures, suggesting dopaminergic regulation of hormone secretion by black cohosh.

Osteopenia Inhibition

The black cohosh extract BNO 1055 (60 mg/rat, SC) has been shown to increase the expression of collagen I and osteocalcin in rats in a manner similar to that produced by 8 μg of estradiol in ovx rats (79). An additional study using BNO 1055 demonstrated an osteoprotective effect as shown by a reduced loss of bone mineral density in rat tibia after 3 months of administration (81). A study using an unspecified isopropanol extract of black cohosh showed reduced urinary markers of bone loss. The authors

Table 1 Selected Black Cohosh Clinical Studies

Author (reference no.)	Year	Extract/formulation/dosage	Study length	N	Outcome measure/result	Study design
Kesselkaul (110)	1957	Remifemin [®] 60 drops	2 wk	63	Alleviation of climacteric complaints in 95% of patients	Case series
Schotten (111)	1958	Remifemin 20 drops	3–4 wk	22	Alleviation of neurovegetative and psychic complaints associated with menopause and premenopause	Case series
Foldes (53)	1959	Remifemin, 3 tablets/day	Unknown	41	31 patients of the <i>verum</i> group responded to the treatment with a decrease in menopausal complaints	Placebo, controlled, open, crossover, patient self-assessment
Starfinger (112)	1960	Remifemin, 3–20 drops/day	1 yr	105	Decreased climacteric complaints without incidence of side effects or resulting in nonphysiological bleeding	Case series
Brucker (113)	1960	Remifemin, tablets, variable dose	Variable	87 (517)	Alleviation of menopausal complaints	Case series
Heizer (114)	1960	Remifemin, tablets 3–6/day	2–18 mo	66	Alleviation of menopausal (neurovegetative and psychic) complaints in 47% of patients with intact uteri and 35% with hysterectomies	Case series
Gorlich (115)	1962	Remifemin, tablets, variable dose	Variable	41 (258)	Alleviation of climacteric and vascular symptoms in 85% of patients	Case series
Schildge (116)	1964	Remifemin, fluid extract 60 drops/day	Variable	135	Euphoric and mild sedative-calming effects in all pts	Case series
Stolze (117)	1982	Remifemin, fluid extract 80 drops/day	6–8 wk	629	Alleviation of neurovegetative and psychological menopausal symptoms in 80% of patients	Open, physician and patient self-assessment
Daiber (118)	1983	Remifemin, fluid extract 80 drops/day	12 wk	36	Alleviation of climacteric complaints (hot flashes, insomnia, sweating, and restlessness)	Open, KMI, CGI
Vorberg (119)	1984	Remifemin, fluid extract 80 drops/day	12 wk	50	Significant or highly significant alleviation of menopausal (neurovegetative and psychic) complaints; study included subjects contraindicated to hormone therapy	Randomized, open, KMI, CGI, POMS
Warnecke (120)	1985	Remifemin, fluid extract 80 drops/day	12 wk	20	Significant alleviation of symptoms (psychic and neurovegetative) in the black cohosh, conjugated estrogen, and diazepam groups. Vaginal cytology of treatment group was comparable to estrogenic stimulation	Randomized, open, KMI, HAM-A, SDS, CGI, karyopyknosis index, eosinophil index
Stoll (121)	1987	Remifemin, tablets equivalent to 8 mg extract/day	12 wk	26	Significant alleviation of climacteric symptoms (vaginal atrophy, neurovegetative and psychic complaints) in comparison with estrogen and placebo groups	Double-blinded, randomized, placebo-controlled, KMI, HAM-A, VMI (vaginal epithelium)
Petho (122)	1987	Remifemin, tablets, unspecified dose	6 mo	50	KMI decreased significantly from 17.6 to 9.2, correlates with a significant reduction in neurovegetative symptoms. Severity of subjective self-assessments of subjects physical and psychological symptoms decreased	Open, KMI, patient self-assessment
Lehman-Willenbrock and Riedel (123)	1988	Remifemin, tablets equivalent to 8 mg extract/day	6 mo	15	Significant alleviation of climacteric symptoms in black cohosh and drug treatment groups. No significant change in gonadotropin (FSH, LH) levels	Randomized, open, KMI
Duker et al. (75)	1991	Remifemin, tablets equivalent to 40 mg dried herb/day	2 mo	110	LH suppression	In vitro study using blood from menopausal women taking black cohosh

Table 1 Selected Black Cohosh Clinical Studies (Continued)

Author (reference no.)	Year	Extract/formulation/dosage	Study length	N	Outcome measure/result	Study design
Baier-Jagodinski (124)	1995	Cimisan [®] T Tropfen, variable dose	4–8 wk	157	89% of patients showed symptom improvement after 4 wk. At final visit, the efficacy was assessed as very good, 40%; good, 41%; sufficient, 12%; inadequate, 7%	Open, uncontrolled
Mielnik (69)	1997	Uncharacterized extract, 4 mg daily	6 mo	34	Alleviation of climacteric (neurovegetative) symptoms in 76% of patients after 1 mo	Open, KMI
Georgiev and Iordanova (70)	1997	Uncharacterized extract, unspecified dose	3 mo	50	Alleviation of climacteric symptoms in 90% of patients. Increase in vaginal cell proliferation (VMI) in 40% of treated women	Open, KMI, HAM-A, VMI
Nesselhut and Liske (125)	1999	Remifemin, tablets, equivalent to 136 mg dried herb/day	3 mo	28	Good to very good alleviation of 10 menopausal symptoms in 80% of study participants	Open, postmarket surveillance
Jacobson, et al. (63)	2001	Remifemin, tablets equivalent to 40 mg dried herb/day	60 days	42 ^a	No change in median number or intensity of hot flashes	Double blinded, randomized, placebo controlled, patient self-assessment, VAS, MSS
Liske et al. (67)	2002	Unique <i>Cimicifuga racemosa</i> preparation, equivalent to 39 or 127.3 mg/day	6 mo	152	No direct systemic estrogenic effect on serum levels of FSH, LH, SHBG, prolactin, and 17- β estradiol. No change in vaginal cytology. Higher dose had a more significant reduction in KM index after 6 mo. Significant reduction with both doses in neurovegetative and psychic complaints	Drug equivalence trial, KMI, SDS, CGI
Hernandez Munoz and Pluchino (66)	2003	BNO 1055	12 mo	136	Combination therapy with tamoxifen (20 mg) reduced severity and incidence of hot flashes	Open, randomized, patient self-assessment
Wuttke et al. (64)	2003	Klimadynon [®] /BNO 1055	3 mo	62	Equipotent to 0.6 CE for relief of climacteric complaints and for bone resorption. No effect on endometrial thickness	Randomized, double blinded, placebo controlled, multicenter, MRS
Verhoeven et al. (126)	2005	125 mg soy extract daily (providing 50 mg isoflavones including 24 mg genistein and 21.5 mg daidzein), 1500 mg evening primrose oil extract (providing 150 mg gamma linoleic acid), 100 mg <i>Actaea racemosa</i> L. extract (providing 8 mg deoxyacetein), 200 mg calcium, 1.25 mg vitamin D, and 10 IU vitamin E, placebo group received 2000 mg olive oil daily	12 wk	124	Subjects were experiencing at least five vasomotor symptoms every 24 hr at study entry. At weeks 6 and 12, all scores in both groups had improved compared with baseline, though the overall difference in scores between the groups was not statistically significant	Multicenter, randomized, placebo-controlled, double-blind study, Kupperman index and Greene Climacteric scale
Nappi et al. (127)	2005	Aqueous isopropanolic extract 40 mg/day	3 mo	64	Postmenopausal women were recruited. Both CR and low-dose TTSE2 significantly reduced the number of hot flushes per day ($P < 0.001$) and vasomotor symptoms ($P < 0.001$), starting at the first month of treatment. Such a positive effect was maintained throughout the 3 mo of observation, without any significant difference between the two treatments. An identical effect was evident also for both anxiety ($P < 0.001$) and depression ($P < 0.001$), which were significantly reduced following 3 mo of both CR and low-dose TTSE2. Total cholesterol was unchanged by CR treatment but significantly ($P < 0.033$) reduced by 3 mo of low-dose TTSE2. A slight but significant increase of HDL cholesterol	Randomized, controlled, clinical study

(continued)

Table 1 Selected Black Cohosh Clinical Studies (Continued)

Author (reference no.)	Year	Extract/formulation/dosage	Study length	N	Outcome measure/result	Study design
					($P < 0.04$) was found only in women treated with CR, while LDL-cholesterol levels were significantly lowered by 3 mo of both CR ($P < 0.003$) and low-dose TTSE2 ($P < 0.002$). Triglyceride levels were not affected by both treatments nor was liver function. FSH, LH, and cortisol were not significantly affected after the 3-mo treatment, while PRL ($P < 0.005$) and 17- β -E2 ($P < 0.001$) were increased slightly only by low-dose TTSE2. Endometrial thickness was not affected by either CR or low-dose TTSE2	
Frei-Kleiner et al. (128)	2005	6.5 mg dry rhizome extract; 60% ethanol extraction solvent. Dose = 1 cap daily	12 wk	122	Menopausal women were recruited. The primary efficacy analysis showed no superiority of the tested black cohosh extract compared with placebo. However, in the subgroup of patients with a Kupperman index $> \text{or} = 20$ a significant superiority regarding this index could be demonstrated ($P < 0.018$). A decrease of 47% and 21% was observed in the black cohosh and placebo group, respectively. The weekly weighted scores of hot flashes ($P < 0.052$) and the Menopause Rating Scale ($P < 0.009$) showed similar results. Prevalence and intensity of the adverse events did not differ in the two treatment groups	Multicenter, randomized, placebo-controlled, double-blind, parallel group study
Pockaj et al. (61)	2006	20 mg <i>C. racemosa</i> and rhizome extract standardized to contain 1 mg of triterpene glycosides as calculated by 27-deoxyacetin, placebo	Two 4-wk crossover treatment periods	132	Toxicity was minimal and not different by treatment group. Patients receiving black cohosh reported a mean decrease in hot flash score of 20% (comparing the fourth treatment week with the baseline week) compared with a 27% decrease for patients on placebo ($P = 0.53$). Mean hot flash frequency was reduced 17% on black cohosh and 26% on placebo ($P = 0.36$). Patient treatment preferences were measured after completion of both treatment periods by ascertaining which treatment period, if any, the patient preferred. Thirty-four percent of patients preferred the black cohosh treatment, 38% preferred the placebo, and 28% did not prefer either treatment	Double-blind, randomized, crossover clinical trial. Primary end point was the average inpatient hot flash score (a construct of average daily hot flash severity and frequency) difference between the baseline week and the last study week of the first treatment period. Green Climacteric scale
Newton et al. (HALT) (62)	2006	(i) Black cohosh, 160 mg daily; (ii) multibotanical with black cohosh, 200 mg daily, and 9 other ingredients; (iii) multibotanical plus dietary soy counseling; (iv) conjugated equine estrogen, 0.625 mg daily, with or without medroxyprogesterone acetate, 2.5 mg daily; or (v) placebo	1 yr	351	Women aged 45–55 yr with two or more vasomotor symptoms per day were recruited. Vasomotor symptoms per day, symptom intensity, Wiklund Vasomotor Symptom Subscale score did not differ between the herbal interventions and placebo at 3, 6, or 12 mo or for the average over all the follow-up time points ($P > 0.05$ for all comparisons) with 1 exception: At 12 mo, symptom intensity was significantly worse with the multibotanical plus soy intervention than with placebo ($P > 0.016$). The difference in vasomotor symptoms per day between placebo and any of the herbal treatments at any time point was less than one symptom per day; for the average over all the follow-up time points, the difference was less than 0.55 symptom per day. The difference for hormone therapy versus placebo was -4.06 vasomotor symptoms per day for the average over all the follow-up time points (95% CI, -5.93 to -2.19 symptoms per day;	Randomized, double-blind, placebo-controlled trial. Wiklund Vasomotor Symptom scale

Table 1 Selected Black Cohosh Clinical Studies (Continued)

Author (reference no.)	Year	Extract/formulation/dosage	Study length	N	Outcome measure/result	Study design
					$P > 0.001$). Differences between treatment groups smaller than 1.5 vasomotor symptoms per day cannot be ruled out. Black cohosh containing therapies had no demonstrable effects on lipids, glucose, insulin, or fibrinogen (124)	
Raus et al. (129)	2006	Dried aqueous/ethanolic (58% vol/vol) extract CR BNO 1055 of the rhizome of <i>Actaea</i> or CR (black cohosh)	1 yr	400	Postmenopausal women with symptoms related to estrogen deficiency were recruited. The lack of endometrial proliferation and improvement of climacteric complaints as well as only a few gynecologic organ-related adverse events are reported for the first time after a treatment period of 1 yr	Prospective, open-label, multinational, multicenter study. Endovaginal ultrasonography
Sammartino et al. (130)	2006	Group A ($n = 40$) was treated with 1 tablet/day per os containing a combination of isoflavones [soy germ extracts, Glycine max, no OGM-SoyLife: 150 mg, titrated in isoflavones (40%) = 60 mg], lignans [flaxseed extracts, <i>Linum usitatissimum</i> , no OGM-LinumLife: 100 mg, titrated in lignans (20%) = 20 mg] and <i>C. racemosa</i> [50 mg, titrated in triterpene (2.5%) = 1.25 mg] (Euclim [®] ; Alfa Wassermann, Italy); group B ($n = 40$) was treated with calcium supplements (Metocal, Rottapharm, Monza, Italy)	Three cycles of 28 days	80	Healthy postmenopausal women were recruited. At baseline no significant difference was detected in KI between groups A and B; however, after three cycles of treatment, KI was significantly ($P > 0.05$) lower in group A compared with baseline and with group B	Double-blind, randomized, placebo-controlled trial, Kupperman index
Gurley et al. (131)	2006	Milk thistle (300 mg, three times daily, standardized to contain 80% silymarin), black cohosh extract (20 mg, twice daily, standardized to 2.5% triterpene glycosides), rifampin (300 mg, twice daily), and clarithromycin (500 mg, twice daily)	14 days	16	Young adults (8 females) (age, mean \pm SD = 26 ± 5 yr; weight, 75 ± 13 kg) compared with the effects of rifampin and clarithromycin, the botanical supplements milk thistle and black cohosh produced no significant changes in the disposition of digoxin, a clinically recognized P-gp substrate with a narrow therapeutic index. Accordingly, these two supplements appear to pose no clinically significant risk for P-gp-mediated herb-drug interactions	Randomized controlled, clinical pharmacokinetic trial
Rebbeck et al. (132)	2007	Varied	Case-control design	949 breast cancer cases; 1524 controls	HRS varied significantly by race, with African American women being more likely than European American women to use any herbal preparation (19.2% vs. 14.7%, $P = 0.003$) as well as specific preparations including black cohosh (5.4% vs. 2.0%, $P > 0.003$), ginseng (12.5% vs. 7.9%, $P < 0.001$) and red clover (4.7% vs. 0.6%, $P < 0.001$). Use of black cohosh had a significant breast cancer protective effect (adjusted odds ratio 0.39, 95% CI: 0.22–0.70). This association was similar among women who reported use of either black cohosh or Remifemin (a herbal preparation derived from black cohosh; adjusted odds ratio 0.47, 95% CI: 0.27–0.82)	Population-based case-control study

(continued)

Table 1 Selected Black Cohosh Clinical Studies (Continued)

Author (reference no.)	Year	Extract/formulation/dosage	Study length	N	Outcome measure/result	Study design
Hirschberg et al. (133)	2007	Remifemin (batch no. 229690), one tablet twice daily. Each tablet contains 0.018–0.026 mL liquid extract of black cohosh rootstock (0.78–1.14:1) corresponding to 20 mg herbal drug [i.e., 2.5 mg dry extract, extraction agent isopropanol 40% (vol/vol)], 40 mg/day	6 mo	74	None of the women showed any increase in mammographic breast density. Furthermore, there was no increase in breast cell proliferation. The mean change \pm SD in proportion of Ki-67-positive cells was $0.5\% \pm 2.4\%$ (median, 0.0; 95% CI = -1.32 – 0.34) for paired samples. The mean change in endometrial thickness \pm SD was 0.0 ± 0.9 mm (median, 0.0). A modest number of adverse events were possibly related to treatment, but none of these were serious. Laboratory findings and vital signs were normal	Prospective, open, uncontrolled drug safety study
Chung et al. (71)	2007	Gynoplus (264 mg tablet with 0.0364 mL <i>Cimicifuga racemosa</i> rhizome, equivalent to 1 mg terpene glycosides; 84 mg dried <i>Hypericum perforatum</i> extract, equivalent to 0.25 mg hypericin, with 80% methanol)	12 wk	89	Kupperman index (KI) for climacteric complaints. Vaginal maturation indices, serum estradiol, FSH, LH, total cholesterol, HDL-cholesterol, LDL-cholesterol, and triglyceride levels. Significant improvements in climacteric symptoms and hot flashes, as well as an increase in HDL (from 58.32 ± 11.64 to 59.74 ± 10.54) were observed in the Gynoplus group by 4 wk and maintained after 12 wk, compared with the placebo group. There was no significant impact on superficial cell proportion	Randomized, double-blind, placebo-controlled trial
Ruhlen et al. (22)	2007	Remifemin R and CimiPure (2.5% triterpenes; 40 mg capsule contains 1 mg 23- <i>epi</i> -26-deoxyactein)	12 wk followed by 12 wk washout	61	Subjects experienced relief of menopausal symptoms, with reversion to baseline after washout. No effect on serum estrogenic markers. No effect on pS2 or cell morphology in nipple aspirate	Open study
Gurley et al. (134)	2008	Milk thistle (300 mg, three times daily, standardized to contain 80% silymarin), black cohosh extract (40 mg, twice daily, standardized to 2.5% triterpene glycosides), rifampin (300 mg, twice daily), and clarithromycin (500 mg, twice daily)	14 days	19	Young adults [9 women; age (mean \pm SD) = 28 ± 6 yr; weight = 76.5 ± 16.4 kg]. Milk thistle and black cohosh appear to have no clinically relevant effect on CYP3A activity in vivo. Neither spontaneous reports from study participants nor their responses to questions asked by study nurses regarding supplement/medication usage revealed any serious adverse events	Randomized controlled, clinical pharmacokinetic trial
Amsterdam et al. (73)	2009		12 wk	28 (15 treatment/13 placebo)	The primary outcome measure was changed over time in total HAM-A scores. Secondary outcomes included a change in scores on the Beck Anxiety Inventory, Green Climacteric Scale (GCS), and Psychological General Well-Being Index (PGWBI) and the proportion of patients with a change of 50% or higher in baseline HAM-A scores. There was neither a significant group difference in change over time in total HAM-A scores ($P = 0.294$) nor a group difference in the proportion of subjects with a reduction of 50% or higher in baseline HAM-A scores at study end point ($P = 0.79$). There was a significantly greater reduction in the total GCS scores during placebo (vs. black cohosh; $P = 0.035$) but no group difference in change over time in the GCS subscale scores or in the PGWBI ($P = 0.140$). One subject (3.6%) taking black cohosh discontinued treatment because of adverse events	Randomized, double-blind, placebo-controlled trial

Table 1 Selected Black Cohosh Clinical Studies (Continued)

Author (reference no.)	Year	Extract/formulation/dosage	Study length	N	Outcome measure/result	Study design
Geller et al. (72)	2009		12 mo	89	Primary outcome measures were reduction in vasomotor symptoms (hot flashes and night sweats) by black cohosh and red clover compared with placebo; secondary outcomes included safety evaluation, reduction of somatic symptoms, relief of sexual dysfunction, and overall improvement in quality of life. Reductions in number of vasomotor symptoms after a 12-mo intervention were as follows: black cohosh (34%), red clover (57%), placebo (63%), and CEE/MPA (94%), with only CEE/MPA differing significantly from placebo. Black cohosh and red clover did not significantly reduce the frequency of vasomotor symptoms as compared with placebo. Secondary measures indicated that both botanicals were safe as administered. In general, there were no improvements in other menopausal symptoms	Randomized, double-blind, placebo-controlled trial

Abbreviations: CGI, Clinician's Global Impression scale; HAM-A, Hamilton Anxiety scale; KMI, Kupperman Menopausal Index; MSS, unspecified menopausal index using the Likert scale; Open, open-labeled; POMS, Profile of Mood States Scale; SDS, Self-Assessment Depression scale; VAS, Visual Analog Scale; VMI, Vaginal Maturity Index.

of this study suggested the action was similar to that of the SERM Raloxifene (86). A follow-up study using BNO 1055 versus CE therapy showed beneficial effects of the extract on bone metabolism in humans, specifically an increase in bone-specific alkaline phosphatase in serum (64). While no direct correlation between species has been established, it is of note that studies of Asian *Cimicifuga* species have demonstrated similar activity and may be of importance for further investigation of this biological activity (87,88).

Uterine Weight/Estrous Induction

Uterine and ovarian weight increase, cell cornification, and an increased duration of estrous are generally considered evidence of endometrial estrogenic activity. However, it has recently been proposed that uterine weight is a poor marker for endometrial effects (89). Three studies demonstrating that black cohosh extracts increased the uterine weight of ovx rats have been reported (50,77,90) with two of the studies using an undescribed root extract (77,90). One study on immature mice reported similar findings (50). By contrast, two studies on ovx rats (79,91), as well as four studies on immature mice, reported the converse (79,81,83,92). One of these studies found that although there was no increase in uterine or ovarian weight, the duration of estrous was significantly increased by black cohosh (92). A subsequent study by the authors and collaborators demonstrated no attenuation in uterine weight at variable doses (4, 40, and 400 mg/kg/day) of a 40% isopropanol extract in ovx rats (4).

Cell Proliferation

An unspecified black cohosh extract failed to significantly induce growth of MCF-7 cells when compared with untreated control cells (81). A study using isopropanolic and

ethanolic extracts also failed to induce growth of MCF-7 cells (93).

CNS Effects and Neurotransmitter Binding

A murine study using an unspecified extract (25–100 mg/kg, orally) measured effects on body temperature and ketamine-induced sleep time using bromocriptine (D₂-agonist) as a positive control. Pretreatment with sulpiride (D₂ blocker) suggested a receptor-mediated dopaminergic effect (84). An additional mouse study was carried out to characterize neurotransmitter levels in the striatum and hippocampus after pretreatment with the extract for 21 days (94). Serotonin and dopamine metabolic levels in the striatum were substantially lower in comparison with the control group. These studies have led to the hypothesis that dopaminergic, rather than estrogenic, activity is responsible for the reported success of black cohosh in reducing climacteric symptoms (95,96). A study by the authors and collaborators has pointed to the effects of black cohosh being mediated by serotonin (5-HT) receptors (4). Three different extracts (100% methanol, 40% isopropanol, 75% ethanol) were found to bind to the 5-HT₇-receptor subtype at IC₅₀ ≤ 3.12 µg/mL. The 40% isopropanol extract inhibited (³H)-lysergic acid diethylamide binding to the 5-HT₇ receptor with greater potency than (³H)-8-hydroxy-2-(di-*N*-propylamino)tetralin to the rat 5-HT_{1A}. Analysis of ligand-binding data suggests that the methanol extract functioned as a mixed competitive ligand of the 5HT₇ receptor. Further testing of the methanol extract in 293T-5-HT₇ transfected HEK cells raised cAMP levels; these raised levels were reversed in the presence of the 5-HT antagonist methiothepin, indicating a receptor-mediated process and possible agonist activity local to the receptor (4).

Antioxidant

A black cohosh methanol extract protected S30 breast cancer cells against menadione-induced DNA damage at variable concentrations and scavenged DPPH free radicals at a concentration of 99 μ M (38).

USE IN PREGNANT/LACTATING WOMEN

Despite an absence of mutagenic effects reported to date, the use of black cohosh during pregnancy is contraindicated according to WHO suggestions (97). Data are inconclusive regarding the effects on lactation.

DOSAGE (97,98)

Recommended doses for black cohosh are as follows:

1. Dried rhizome and root: 1 g up to three times daily.
2. Tincture (1:10): 0.4 mL daily (40–60% alcohol vol/vol).
3. Fluid extract (1:1): 20 drops twice daily (60% ethanol vol/vol, equivalent to 40 mg dried herb).
4. Tablet equivalence: two tablets a day (equivalent to 40 mg dried extract).

The Commission E monograph also recommends that usage not be extended for more than 6 months due to a lack of long-term safety data. Experimental data are not available to suggest this 6-month limit.

ADVERSE EFFECTS/SAFETY

A majority of adverse event reports (AERs) for black cohosh have been associated with Remifemin products, probably due to its widespread use. Thus, the AER data may speak more to the safety of this particular product rather than black cohosh extracts in general. In clinical trials, minor cases of nausea, vomiting, dizziness, and headaches have been reported (61–73). An analysis of the safety data from published clinical trials, case studies, postmarketing surveillance studies, spontaneous report programs, and phase I studies was carried out (99). The data obtained from more than 20 studies, including more than 2000 patients, suggest that adverse event occurrence with black cohosh is rare, and that such events are mild and reversible, the most common being gastrointestinal upset and rashes. The same review investigated black cohosh preparation and AERs and concluded that adverse events are rare, mild, and reversible (99).

That said, black cohosh has garnered a great deal of attention with respect to its safety over the past 5 years, with the emergence of a few case reports citing acute hepatitis, convulsions, cardiovascular, and circulatory insult (100–104). It is important to note that in a number of these reports, no effort was made to positively identify the botanical associated with the event as black cohosh. In one case, depositions taken during a legal proceeding revealed that the lack of alcohol consumption and concomitant medications reported in a published case report (101) was inaccurate (105). Underreporting of adverse effects may also be a common problem with botanical supplement (100–104). However, these case reports have gen-

erated much interest within the research community, so much so that two workshops have been convened by the National Institutes of Health (NIH) on the specific issue of the safety of black cohosh preparations: one workshop sponsored by the National Center for Complementary and Alternative Medicine (NCCAM) and the Office of Dietary Supplements (ODS) in November 2004 and a more recent workshop sponsored by the ODS held in June 2007. The report from the 2004 workshop indicated that there is “no plausible mechanism of liver toxicity.” The 2007 workshop offered no conclusions on safety to contradict those of the 2004 meeting regarding hepatotoxicity of black cohosh preparations. The 2007 workshop did recommend that active steps be taken to monitor liver health in human clinical trials of black cohosh (106).

It is also noteworthy that in the 2004 workshop, it was agreed that “suspected hepatotoxicity should not be broadcast when toxicity has not been demonstrated.” Despite concerns by some scientists, a warning statement on commercial black cohosh product labels was mandated in Australia by the Therapeutic Goods Administration (TGA), and the European Medicines Agency (EMA) released a press statement on July 18, 2006, urging patients to stop taking black cohosh if they develop signs suggestive of liver injury. It is noteworthy that it is not clear and has never been fully disclosed as to how these agencies reached their decision and what the scientific data were that led to these warning statements.

While the notion of idiosyncratic hepatotoxicity was raised in the June 2007 workshop by toxicologists from the Food and Drug Administration (FDA), it was acknowledged by these toxicologists that without data from a mandatory adverse event reporting system, no real conclusion on causality regarding idiosyncratic hepatotoxicity can be drawn from case reports.

In the September–October 2007 edition of USP’s Pharmacopeial Forum (100), the USP proposed the addition of a cautionary statement for USP quality black cohosh products with regard to liver toxicity. The American Botanical Council (ABC) responded that given the long history of safe black cohosh use and the lack of clear scientific evidence for toxicity, there is not enough information for such a warning. The ABC noted that of the 42 case reports of toxicity cited by the USP, only 18 met criteria for assessment based on a standard-rating scale, and of these, 3 met criteria for “possible” toxicity, and 2 for “probable” toxicity. Many case reports were also said to lack adequate documentation regarding the actual identity of the black cohosh used and possible confounding factors (107).

COMPENDIAL/REGULATORY STATUS

Black cohosh products are regulated and marketed in the United States as dietary supplements under the provisions of the Dietary Supplement Health and Education Act (DSHEA) of 1994 (U.S.C. § 321). Dried black cohosh rhizome and roots, powdered black cohosh, black cohosh fluid extract, powdered black cohosh extract, and black cohosh tablets now have official standing in dietary supplement monographs in the *United States Pharmacopoeia—National Formulary* (108). In the European Union nations,

black cohosh products are approved as nonprescription phytomedicines when administered orally in compliance with the German Commission E monographs (109).

CONCLUSIONS

With the elevated concern surrounding side effects related to classical hormone/estrogen therapy for menopause, modulation of certain climacteric symptoms of menopause by both dopaminergic and serotonergic drugs is becoming a more viable and frequent treatment option. A review of the clinical trials associated with black cohosh leads to the conclusion that women using hydroalcoholic extracts of the rhizomes and roots of this plant may gain relief from climacteric symptoms (i.e., hot flashes) in comparison with placebo over the short term, whereas longer studies have not shown the same degree of efficacy. Further clouding the review of these clinical trials is the wide variety and different types of extracts administered in published studies. Early in vitro studies reported that black cohosh extracts acted on ERs or had a sort direct effect on ERs. Now it is becoming clear that the beneficial effect of reducing hot flashes is related, at least in part, to serotonergic or dopaminergic mechanisms that regulate hypothalamic control and possibly mediate estrogenic mechanisms. As mentioned earlier, the controversy surrounding a purported direct estrogenic mechanism of action may also be due to variance in the extracts assayed. Overall, given variation in trial length, extract types, and other potential confounders, the efficacy of black cohosh as a treatment for menopausal symptoms is uncertain and further rigorous trials seem warranted.

Blue-Green Algae (Cyanobacteria)

Wayne W. Carmichael and Mary Stukenberg with Joseph M. Betz

INTRODUCTION

In Asia, Africa, and parts of Central/South America, naturally occurring green and blue-green algae have been harvested and consumed for their nutritive properties for centuries. In western cultures, for approximately 30 years, certain fresh water blue-green algae (cyanobacteria) have been accepted as a source of food, in particular *Spirulina* (*Arthrospira*) *platensis* and *Spirulina maxima*. Beginning in the early 1980s, another blue-green species, *Aphanizomenon flos-aquae* (AFA), was adopted for similar uses. Both are rich in proteins, vitamins, essential amino acids, minerals, and essential fatty acids. Consumers of blue-green algae report a wide variety of putative effects, such as mental clarity, increased energy, blood and colon cleansing, increased focus, particularly in children with attention deficit disorder, improved digestion, increased eye health, healthier joints, and tissues. In the past 10 years, owing largely to the strong anecdotal consumer testimony about them, studies have been conducted to verify not only their nutritional efficacy but also their potential pharmaceutical benefits as well.

BACKGROUND

Worldwide, algae, for thousands of years, have been a food source and treatment for various physical ailments. In coastal regions of the Far East, recorded use of macroalgae (sea weed) as a food source began approximately 6000 BC, with evidence that many species were used for food and medical treatment by around AD 900. The Spanish recorded the use of microalgae as a food source when they reported that the natives of Lake Texcoco collected cyanobacteria from the waters of the lake to make sun-dried cakes. In present day Africa, local tribes harvest cyanobacteria in the Lake Chad region, primarily *Spirulina*, and also use it to make hard cakes, called *dihe*. In some regions of Chad, people consume from 9 to 13 g/meal, constituting 10% to 60% of the meal. However, the longest recorded use of cyanobacteria as food is the consumption of *Nostoc flagelliforme* in China, where there are records of its use for some 2000 years and where it is still harvested on a large scale. Use of microalgae in the western culture began in the 1970s. Most commercial producers of microalgae are located in the Asia-Pacific rim, where approximately 110 commercial producers of microalgae have an annual production capacity from 3 to 500 tons. These cultivated microalgae include *Chlorella*, *Spirulina*, *Dunaliella*, *Nannochloropsis*, *Nitzschia*,

Crypthecodinium, *Tetraselmis*, *Skeletonema*, *Isochrysis*, and *Chaetoceros*.

Within the cyanobacteria, *Spirulina* (*Arthrospira*) *platensis* and *S. maxima* have been commercially produced as a human and animal food supplement and food coloring for approximately 30 years. *Spirulina* is cultured in constructed outdoor ponds in Africa, California, Hawaii, Thailand, China, Taiwan, and India. World production in 1995 was approximately 2×10^6 kg.

The newest cyanobacterium to be used as a food supplement is AFA, the production of which differs significantly from *Spirulina*, because it is harvested from a natural lake rather than constructed ponds. Since the early 1980s, this alga has been harvested from Upper Klamath Lake, Oregon, and sold as a food and health food supplement. The popularity of both *Spirulina* and AFA blue-green algae products over other seaweeds and green algae may be attributable to the convenience of its packaging and consumption, as well as to its highly directed marketing to the health-conscious consumer. In 1998, the market for AFA as a health food supplement was approximately US \$100 million with an annual production greater than 1×10^6 kg (dry weight) (1–18).

Chemistry and Preparation

Edible blue-green algae are nutrient dense food. The features common to all blue-green algae include a high content of bioavailable amino acids and minerals, such as zinc, selenium, and magnesium. The nutrient profile is subject to variation by habitat, harvest procedure, quality control for contaminating species, proper processing to preserve nutrients, and storage conditions, all of which influence the vitamin content and antioxidant properties delivered by the final product. However, the appeal of blue-green algae is their raw, unprocessed nature and their abundance of carotenoids, chlorophyll, phycocyanins, phytosterols, glycolipids, γ -linolenic acid, and other bioactive components (19–21).

Approximately, 40 cyanobacteria species and genera produce potent toxins. *Spirulina* products have not been associated with toxicity reports in humans, largely owing to its being grown under cultured conditions (22). Natural samples and cultured strains of AFA have been reported to produce neurotoxins including paralytic shellfish poisons (neosaxitoxin and saxitoxins) and anatoxin-a. Recent work seems to indicate that a different *Aphanizomenon* species is the toxin producer. *A. flos-aquae* has been reported to be dominant or codominant in water blooms containing *Microcystis* and *Anabaena* and is found in many eutrophic water bodies. Species of *Microcystis* can produce a family

of potent liver toxins called microcystins. *Cylindrospermopsis* is a hepatotoxic and nephrotoxic compound produced by several freshwater cyanobacteria, including *Cylindrospermopsis raciborskii* and *Anabaena* spp (23). Several species of marine and freshwater cyanobacteria (including a number of *Nostoc*, *Anabaena*, and *Microcystis* species) produce the neurotoxic amino acid BMAA (β -N-methylamino-L-alanine) (24). Although these toxic substances are probably not naturally present in the target species discussed below, the possibility that they might be present as contaminants in commercial products highlights the need for rigorous quality-control measures.

Blue-green algae products most often come in a tablet form as algal material directly compressed. The tablets can contain fillers such as sugars or starches called binders, which give shape and stability to the tablets. Algae supplements also come in a capsule form to neutralize the taste and make the product easier to swallow, or can be bought by the pound in powder form or in liquid extract forms. Some companies combine the algae in "green supplements" that contain other health-enhancing ingredients such as alfalfa sprouts. Supplements come in kosher or vegetarian forms, and can be combined with digestive aids. Recommended dosages of blue-green algae products vary widely, but can be as much as 20 g/day. On the average, companies that produce algal products for consumption as nutritional supplements recommend 500 mg to 1 g/day to start, with a build up over time to several grams a day, often without an upper limit on consumption (25,26).

Efficacy

Two types of blue-green algae form the major nutritional supplement groups, *Spirulina* and AFA. As the traits of each vary slightly, they are addressed separately below.

Spirulina

The blue-green alga *Spirulina* was so named for its helically coiled trichomes or rows of cells. Until recently, *Spirulina* and *Arthrospira* were thought to belong to separate genera, and the distinction was thought to be especially important as only the strains of *Arthrospira* had been proven to be safe for human consumption. These two are now referred to as *Arthrospira* in scientific circles. Although the name *Spirulina* has been persisted for commercial labeling, the two are synonymous (27).

Spirulina is generally produced in large outdoor ponds under controlled conditions. The safety of *Spirulina* for human food has been established through long use, and through various toxicological studies done under the auspices of the United Nations Industrial Development Organization (28). *Spirulina* is 60% to 70% protein by weight and contains many vitamins, especially vitamin B₁₂ and β -carotene, and minerals, especially iron and γ -linolenic acid (Table 1). Recent reports suggest that a number of therapeutic effects and pharmaceutical uses are potential benefits of *Spirulina* as well (18).

Most studies of the effects of *Spirulina* on enhanced body function have been performed on animals, and therapeutic effects have been demonstrated in some cases. Conclusive human studies are rare, but those that carry substantive results are cited below.

Table 1 Nutritional Profile of a Commercial *Spirulina* Product

Composition	<i>Spirulina</i> powder
Per 100 g	
Macronutrients ^a	
Calories	382
Total fat	7.1 g
Total carbohydrate	15.5 g
Dietary fiber	6.8 g
Protein	55 g
Essential amino acids (mg)	
Histidine	900
Isoleucine	3170
Leucine	5030
Lysine	2960
Methionine	1290
Phenylalanine	2510
Threonine	2770
Tryptophan	740
Valine	3500
Nonessential amino acids (mg)	
Alanine	4110
Arginine	4130
Aspartic acid	5670
Cystine	580
Glutamic acid	9180
Glycine	2860
Proline	2170
Serine	2670
Tyrosine	2300
Vitamins ^b	
Vitamin A (as 100% β -carotene)	$\geq 200,000$ IU
Vitamin K	548 μ g
Thiamine HCl (Vitamin B-1)	0.13 mg
Riboflavin (Vitamin B-2)	2.55 mg
Niacin (Vitamin, B-3)	14.3 mg
Vitamin B-6 (Pyridox.HCl)	0.77 mg
Vitamin B-12	93 μ g
Minerals ^b	
Calcium	446 mg
Iron	56 mg
Phosphorus	1010 mg
Iodine	39.1 μ g
Magnesium	305 mg
Zinc	1.27 mg
Selenium	19.6 μ g
Copper	0.32 mg
Manganese	3.0 mg
Chromium	91.7 μ g
Potassium	1620 mg
Sodium	815 mg
Phytonutrients ^b	
Phycocyanin	10 g
Chlorophyll	0.9 g
Superoxide dismutase (SOD)	531,000 IU
γ -linolenic acid (GLA)	1180 mg
Total carotenoids	≥ 370 mg
β -Carotene	≥ 120 mg
Zeaxanthin	≥ 95 mg
Other carotenoids	~ 155 mg

This is a natural product and nutrient data may vary from one lot to another. One example of a nutrient profile for Earthrise[®] *Spirulina* Powder, a commercial *Spirulina* product, is shown in the above table.

^aMacronutrient data are based on most recent proximate analysis.

^bThe data indicate minimum values observed over a four-year period except for sodium where the maximum observed value is used.

Nutritional Rehabilitation

A multicenter study of 182 malnourished children, aged 3 months to 3 years, reported that a 5 g/day dose of *Spirulina* (*Arthrospira*) *platensis* had no added benefit over 90 days when compared to traditional renutrition (29).

Four groups of undernourished children under the age of 5 (550 total) were provided with Misola (60% millet flour, 20% soy, 10% peanut, 9% sugar, 1% salt), Misola plus 5 g of *S. platensis*, traditional meals, or traditional meals plus 5 g of *Spirulina*. All diets contained about the same number of kilocalories/day. The authors concluded that Misola, *Spirulina* plus Misola, and *Spirulina* plus traditional diet are all good food supplements for undernourished children, but that Misola plus *Spirulina* were superior to the other combinations (30).

Cardiovascular

In ischemic heart disease patients, *Spirulina* supplementation was shown to significantly lower blood cholesterol, triglycerides, and LDL and very-low density lipoprotein cholesterol, and raise HDL (the so-called "good") cholesterol. A 4 g/day supplementation showed a higher effect in reducing total serum cholesterol and LDL levels than did 2 g/day (31). In a small two-month study of the effects of 1 g/day of *Spirulina* (species not specified) plus medication versus medication alone on lipid parameters in pediatric hyperlipidemic nephritic syndrome patients, Samuels et al. (32) reported that supplementation of medication with *Spirulina* helped reduce increased lipid levels in these patients.

Several studies in healthy populations have shown positive effects on cardiovascular endpoints. Consumption of *Spirulina* was found to reduce total lipids, free fatty acids, and triglyceride levels in a human study involving diabetic patients. A reduction in LDL/HDL ratio was also observed (33). A nonplacebo-controlled open label trial of 36 healthy adults administered 4.5 g/day of *S. maxima* for six weeks reported a hypolipidemic effect, especially on triacylglycerols and LDL = cholesterol, systolic, and diastolic blood pressure were also reduced (34). Effects of 8 g/day *Spirulina* (species not given) versus placebo on health-related endpoints in 78 healthy elderly Koreans were determined in a 16-week double-blinded trial. In the verum group, significant reductions in total plasma cholesterol and interleukin (IL)-6 concentrations were observed, along with increases in interleukin (IL)-2 concentrations and total antioxidant status (35). Juárez-Oropeza et al. (36) reported results of investigations of the effects of *S. maxima* on vascular reactivity in rats and lipid status and blood pressure in healthy humans. The authors suggest that the results of the rat portion of the study indicate that *Spirulina* induces a tone-related increase in endothelial synthesis/release of nitric oxide and of a vasodilating cyclooxygenase-dependent arachidonic acid metabolite (or a decrease in synthesis/release of an endothelial vasoconstricting eicosanoid). In the nonplacebo-controlled study of the effects of 4.5 g/day *Spirulina* on vascular and lipid parameters in 36 human volunteers, the authors reported reductions in blood pressure and plasma lipid concentrations (especially triacylglycerols and LDL-cholesterol).

Immune System Function

Spirulina was found to have a positive effect on the immune system. In a paper presented at a meeting of the Japanese Society for Immunology, volunteers consuming a *Spirulina* drink for two weeks experienced enhanced immune system function, which continued for up to six months after the extract administration was discontinued (37). A follow-up study reported that administration of 50 mL of a hot water extract of *S. platensis* augmented interferon production and natural killer cell (NK) cytotoxicity in more than 50% of 12 healthy human volunteers (38). Results of a study on immunoglobulin-A in human saliva showed a significant correlation between the immunoglobulin-A level in saliva and the amount of *Spirulina* consumed (39).

Much attention has been focused on the potential mitigation of allergies through *Spirulina* intake. A group of Russian researchers are pursuing a patent on their success with the normalization of immunoglobulin-E in children living in radioactive environments (40). In a more recent study of allergic rhinitis patients, the production of cytokines, critical in regulating immunoglobulin-E-mediated allergy, was measured. In a randomized double-blind crossover study versus placebo, allergic individuals were fed daily with either placebo or *Spirulina* at 1000 or 2000 mg for 12 weeks. Although *Spirulina* seemed to be ineffective at modulating the secretion of Th-1 cytokines (one type of the so-called "killer" cells), the study reported that at 2000 mg/day, *Spirulina* significantly reduced IL-4 levels by 32% (41). A six-month double-blind placebo-controlled trial of the effects of 2 g/day of *S. platensis* on allergic rhinitis in 150 otherwise healthy individuals aged 19 to 49 reported that the cyanobacterium treatment significantly improved symptoms and physical findings including nasal discharge, sneezing, nasal congestion, and itching (42).

Cancer

The sole human cancer intervention study involving *Spirulina* intake was done in India on a group of tobacco chewers afflicted with oral leukoplakia. In a study involving 44 subjects in the intervention group and 43 in a placebo group, it was found that supplementation with 1 g of *Spirulina* per day for one year resulted in complete regression of lesions in 45% of the intervention group and in only 7% of the control group. As supplementation with *Spirulina* did not result in an increase in retinal β -carotene, the authors concluded that other components in *Spirulina* may be responsible for the regression of lesions observed (43).

Other Endpoints

A series of four N-of-1 double-blind randomized trials were performed on four individuals who complained of idiopathic chronic fatigue. Each patient was his own control and received three pairs of treatments comprising four weeks of *S. platensis* and four weeks of placebo in doses of 3 g/day. Outcome measures were severity of fatigue measured on a 10-point scale. The score of fatigue was not significantly different between *Spirulina* and placebo (44). A small study compared the effects of *S. platensis* plus a normal diet against soy protein plus normal diet in the prevention of skeletal muscle damage in untrained

student volunteers. Sixteen subjects were divided into two equal groups (7.5 g/day *S. platensis* or soy protein). They were administered the Bruce incremental treadmill exercise prior to treatment, took the intervention for three weeks, and were then readministered the treadmill exercise. Results suggested that ingestion of *Spirulina* (but not soy protein) protected against skeletal muscle damage and may have led to postponement of the time to exhaustion during all-out exercise (45).

Most of the research on *Spirulina*'s efficacy for human nutrition and pharmaceutical use has been concerned with the areas of vitamin and mineral enrichment, immune system function, antioxidant effects, and anticancer and antiviral effects. Although the number of studies referenced by Amha Belay for his *Spirulina* research review article in 1993 contained 41 references, 18 his review in 2002 contained 98, 17 and this chapter has added additional information, few of the human studies in almost any area can be said to be conclusive. Studies are small or very small, and most are open label nonplacebo-controlled studies. A number of the publications do not provide adequate information (many fail to identify the test cyanobacteria to the species level). Interesting results in both the human studies and in vitro and animal studies show that further research is merited.

Adverse Effects

As previously noted, *Spirulina* products have not been associated with toxicity reports in humans, probably because commercial production is via large-scale culture rather than wild harvest (22).

AFA (*Aphanizomenon flos-aquae*)

In western cultures, certain cyanobacteria have been an accepted source of microalgal biomass for food for approximately 30 years, in particular, as discussed earlier, *Spirulina* (*Arthrospira*) *platensis* and *S. maxima*. Beginning in the early 1980s, another species, AFA, was adopted for similar uses. Members of this genus are free floating (planktonic) and occur either singly or form feathery or spindle-shaped bundles, are cylindrical in shape, much longer than they are wide, and contain abundant gas vesicles. They occur in temperate climates and are most abundant in summer and fall (46). The only known commercial harvesting of AFA is from Upper Klamath Lake, the largest freshwater lake system in Oregon. In 1998, the annual commercial production of AFA was approximately 1×10^6 kg. As this species is not cultured like *Spirulina* in outdoor ponds or raceways, it requires very different procedures for harvesting and processing. Other procedures, such as those for removal of detritus and mineral materials, and those for monitoring and reducing the amounts of certain contaminant cyanobacteria, which can produce cyanotoxins, have also become important in quality control and marketing (47). The nutrient profile for AFA is very similar to that for *Spirulina* (Table 2). Consumers of AFA nutritional supplements report a variety of benefits from enhanced energy to boosted immune system function. Cited below are the peer-reviewed human studies extant in the literature confirming certain of these nutritive and pharmaceutical attributes.

Table 2 Nutritional Profile of a Commercial AFA Product

Nutrient	Units	Amount
General composition

Arachidonic acid (AA)	0.1%	0.04 mg/g

One example of a nutrient profile for Cell Tech Super Blue-Green Algae, a commercial AFA product, as of 4-22-05, is shown in the above table.

Circulation and Immune Function

In a study examining the short-term effects of consumption of moderate amounts (1.5 g/day) of AFA on the immune system, it was discovered that AFA resulted in increased blood cell counts when compared to subjects taking a placebo. When the volunteers were grouped into long-term AFA consumers and naïve volunteers, the naïve volunteers exhibited a minor reduction in natural killer cells, and the long-term consumers exhibited a pronounced reduction. It was further determined that AFA does not activate lymphocytes directly, but that it does increase immune surveillance without directly stimulating the immune system. The authors of this study conclude that AFA has a mild but consistent effect on the immune system and could function as a positive nutritional support for preventing viral infections. They also recommend further research into AFA's potential role in cancer prevention (48). In a later report, an aqueous extract of AFA found to contain a novel ligand for CD62L (L-selectin). Consumption of the extract by 12 healthy subjects in a double-blind randomized crossover study caused mobilization of human CD34⁺CD133⁺ and CD34⁺CD133⁻ stem cells (49).

Eye Disease—Blepharospasm and Meige Syndrome

A study to determine whether blue-green algae could be helpful in improving the eyelid spasms associated with essential blepharospasm and Meige syndrome was undertaken by a group of physicians. Although a few patients exhibited a positive effect, for most patients, neither the severity nor the frequency of facial spasms was significantly reduced (50).

Adverse Effects

No cases of human intoxication by AFA were found in the literature. As noted, around 40 cyanobacterial species have been reported to produce potent natural toxins. Certain *A. flos-aquae* strains were long thought to produce neurotoxins including the paralytic shellfish poisons neosaxitoxin and saxitoxin and anatoxin-a. A reevaluation of the species using gene sequencing data led to the conclusion that a different *Aphanizomenon* species was the actual toxin producer (51). While it now seems clear that AFA is not a toxin-producing species, the toxigenic *Aphanizomenon* species seems to be distinguishable from AFA only by the presence or absence of toxins and by genetic sequencing.

No evidence exists to suggest that AFA is a toxin-producing strain (51), but water blooms of AFA may also contain *Microcystis* and *Anabaena*. Species of *Microcystis* can produce a family of potent liver toxins called microcystins, while *Anabaena* species can produce anatoxins and BMAA. The microcystins, especially, are of concern, since hepatic damage caused by this toxin is cumulative. This has led the State of Oregon to set a safe level of microcystin in AFA product from Klamath Lake. Currently this level is set at 1 μ g/g dry weight of product, and was set to correspond to an average daily adult intake for AFA of 2 g. Recently, the cyanobacterial toxin anatoxin-a was reported in 3 of 39 cyanobacterial dietary supplement product samples at concentrations of 2.5 to 33 μ g/g (52). Exposure guidelines have been summarized by Burch (23). This points to the need for rigorous quality-control measures in production of products. These measures may range from existing practices such as modifying the harvesting equipment to exclude *Microcystis*, harvesting the water bloom only at times when *Microcystis* is at a minimum, or developing and using toxin-detecting methods in an integrated testing scheme (47,53,54).

CONCLUSIONS

As a natural source of many vitamins and minerals, proteins, and chlorophyll, it is not surprising that blue-green algae have attracted attention among those interested in natural sources of nutrition. Thousands of people consume blue-green algae in its most popular forms (*Spirulina* and AFA), and as a result, a large body of anecdotal material has existed for many years concerning the positive health benefits of blue-green algae consumption. The volume of the testimony has contributed to a growing interest in recent years in verifying these benefits through scientific research. Beginning with animal and in vitro studies, and moving toward human studies, scientists have only recently begun to investigate some of the positive health effects attested to by long-term consumers of blue-green algae. These include cholesterol reduction, weight loss, enhanced immune system function, regression of cancer-related lesions, and enhancement of blood circulation, as well as many vitamin and mineral benefits. It must be stated, however, that there is an overall paucity of well-designed, controlled human trials using blue-green algal products as interventions.

As the industry relies on self-regulation, it is important to be aware of the quality-control issues involved in harvesting and packaging blue-green algae for consumption, particularly in the case of AFA, which is harvested from the wild. The World Health Organization has determined through current knowledge of microcystin toxins and what it calls a tolerable daily intake (TDI), an estimate of the intake over a lifetime that does not constitute an appreciable health risk. This TDI is derived through existing knowledge of toxin tolerance in mice combined with principles used in defining the health risks of other chemicals. It carries with it a degree of uncertainty owing to the lack of long-term data for the effect of microcystin on humans (55). To be sure that their risk has been minimized as much as possible, consumers of blue-green algae supplements would be wise to check to see that the product has been

tested for toxins, and it has been found to be below the WHO/Oregon Department of Health Regulatory Level of 1 µg/g of microcystin (56).

Boron

Curtiss Hunt

INTRODUCTION

The element boron is essential for all higher plants in phylogenetic kingdom Viridiplantae (1) and at least some organisms in the phylogenetic kingdoms Eubacteria (2), Stramenopila (3), and Animalia (4,5). Specific species in the kingdom Fungi have a demonstrated physiological response to boron, an important finding because Fungi species are thought to share a common ancestor with animals exclusive of plants (6). Physiologic concentrations of the element are needed to support metabolic processes in several species in Animalia. For example, embryological development in fish and frogs does not proceed normally in the absence of boron. There is evidence that higher vertebrates, that is, chicks, rats, and pigs require physiological amounts of boron to assist normal biologic processes including immune function, bone development, and insulin regulation. In humans, boron is under apparent homeostatic control and is beneficial for immune function and calcium and steroid metabolism.

COMMON CHEMICAL FORMS

Boron is the fifth element in the periodic table with a molecular weight of 10.81 and is the only nonmetal in Group III. Organoboron compounds are those organic compounds that contain B–O bonds, and they also include B–N compounds, because B–N is isoelectronic with C–C (7). Organoboron compounds are apparently important in biological systems and are the result of interaction with OH or amine groups. Organoboron complexes occur in plants and are produced in vitro with biomolecules isolated from animal tissues (8).

BORON SPECIATION

Environmental Forms

Boron does not naturally occur free nor bind directly to any element other than oxygen except for trivial exceptions, for example, NaBF_4 (ferrucite) and $(\text{K,Cs})\text{BF}_4$ (avogadrite) (7). Its average concentration in the oceans is 4.6 mg/L and is the 10th most abundant element in oceanic salts (9). Weathering of clay-rich sedimentary rock is the major source of total boron mobilized into the aquatic environment (10). Undissociated boric acid (orthoboric acid) is the predominant species of boron in most natural freshwater systems (10) where most concentrations are below 0.4 mg/L and not lowered by typical treatments for drinking water. The most common commercial compounds of boron are anhydrous, pentahydrate, and decahydrate

(common name: tincal) forms of disodium tetraborate (borax, $\text{Na}_2\text{B}_4\text{O}_7$), colemanite ($2\text{CaO} \cdot 3\text{B}_2\text{O}_3 \cdot 5\text{H}_2\text{O}$), ulexite ($\text{Na}_2\text{O} \cdot 2\text{CaO} \cdot 5\text{B}_2\text{O}_3 \cdot 16\text{H}_2\text{O}$), boric acid (H_3BO_3), and monohydrate and tetrahydrate forms of sodium perborate (NaBO_3) (11).

Inorganic boron, within the concentration range expected for human blood (2–61 μM B; 22–659 ng B/g wet blood) (12), is essentially present only as the monomeric species orthoboric acid (common name: boric acid) $\text{B}(\text{OH})_3$ and borate, that is, $\text{B}(\text{OH})_4^-$ (13). Boric acid is an exclusively monobasic acid and is not a proton donor, but rather accepts a hydroxyl ion (a Lewis acid) and leaves an excess of protons to form the tetrahedral anion $\text{B}(\text{OH})_4^-$ (14):

Within the normal pH range of the gut and kidney, $\text{B}(\text{OH})_3$ would prevail as the dominant species (pH 1: ~100% $\text{B}(\text{OH})_3$; pH 9.3: 50%; pH 11: ~0%) (15).

Biochemical Forms

Many biomolecules contain one or more hydroxy groups and those with suitable molecular structures can react with boron oxo compounds to form boroesters, an important class of biologically relevant boron species. Several types of boron esters exist. Boric acid reacts with suitable dihydroxy compounds to form corresponding boric acid monoesters (“partial” esterification) (Fig. 1) that retain the trigonal-planar configuration and no charge.

In turn, a boric acid monoester can form a complex with a ligand containing a suitable hydroxyl to create a borate monoester (“partial” esterification; monocyclic) (Fig. 2), but with a tetrahedral configuration and a negative charge. A compound of similar configuration and charge is also formed when borate forms a complex with a suitable dihydroxy compound. The two types of boromonoesters can react with another suitable dihydroxy compound to give a corresponding spirocyclic borodiester (“complete” esterification) that is a chelate

Figure 1 Boric acid may complex with a suitable dihydroxy ligand to form a boric acid monoester (“partial” esterification) that retains a trigonal-planar configuration and no charge.

Figure 6 Experimental data indicate that biochemical species with vicinal *cis*-diols bind strongly to boron: (S)-adenosylmethionine (SAM) \equiv diadenosine hexophosphate (Ap₆A) \equiv Ap₅A > Ap₄A > Ap₃A \equiv NAD⁺ > Ap₂A > NADH \equiv 5'ATP > 5'ADP > 5'AMP > adenosine (ADS). Species without these moieties do not bind boron well: 3'AMP \equiv 2'AMP \equiv cAMP \equiv adenine (ADN).

boron; those without these moieties typically do not. Of these animal or human biocompounds examined, SAM has the highest known affinity for boron (8). It is the predominant methyl donor in biological methylations and is therefore a versatile cofactor in various physiologic processes. NAD⁺, an essential cofactor for five sub-classes of oxidoreductase enzymes, also has a strong affinity for boron (23). The di-adenosine-phosphates (Ap_nA) are structurally similar to NAD⁺. Boron binding by Ap₄A, Ap₅A, and Ap₆A is greatly enhanced compared with NAD⁺ but is still less than that of SAM (8). The Ap_nA molecules are present in all cells with active protein synthesis and reportedly regulate cell proliferation, stress response, and DNA repair (24). At physiologic pH, the adenine moieties of Ap_nA are driven together by hydrophobic forces and stack interfacially (25). Stacking of the terminal adenine moieties brings their adjacent ribose moieties into close proximity, a phenomenon that apparently potentiates cooperative boron binding between the opposing riboses (Fig. 6).

Plant-Based Foods

All higher plants require boron and contain organoboron complexes. There may have been considerable evolutionary pressure exerted to select for carbohydrate energy sources that do not interact with boron. Sugars often form intramolecular hemiacetals: those with five-membered rings are called furanoses and those with six-membered rings are called pyranoses. In cases where either five- or six-membered rings are possible, the six-membered ring usually predominates for unknown reasons (26). In general, compounds in a configuration in which there are *cis*-diols on a furanoid ring (e.g., ribose, apiose, and ery-

thritan) form stronger complexes with boron than do those configured to have *cis*-diols predominately on a pyranoid ring (e.g., the pyranoid form of α -D-glucose). D-Glucose reacts with boric acid (27) but the near absence (<0.5%) of an α -furanose form of D-glucose in aqueous solutions (26) suggests that glucose was selected as the aldose for general energy metabolism because of its lower reactivity with boric acid. On the other hand, ribose may have been selected as part of the chemistry of nucleic acid and nucleotide function and apiose for, rather than against, its extraordinary borate-complexing capability.

Recent evidence suggests that the predominant place of boron function in plants is in the primary cell walls where it cross-links rhamnogalacturonan II (RG-II) (Fig. 7), a small, structurally complex polysaccharide of the pectic fraction. RG-IIs have an atom of boron that cross-links two RG-II dimers at the site of the apiose residues to form a borodiester (28). However, this function is not adequate to explain all boron deficiency signs in plants. Twenty-six boron-binding membrane-associated proteins were identified recently in the higher plant, *Arabidopsis thaliana* (29), and boron oxo compounds also form stable ionic complexes with the polyol ligands mannitol, sorbitol, and fructose in liquid samples of celery phloem sap and vascular exudate and phloem-fed nectaries of peach (30).

Dietary Supplements

Boron speciation in dietary supplements varies widely (31) as does the relevant information provided by various dietary supplement manufacturers. It is sometimes listed only in a general manner (e.g., "borates" or "boron"), and occasionally in a more specific manner (e.g., "sodium

Figure 7 Schematic representation of two monomers of the pectic polysaccharide rhamnogalacturonan-II cross-linked by an atom of boron at the site of the apiose residues to form a borodiester. Multiple cross-links form a supramolecular network. Source: From Ref. 75.

borate" or "sodium tetraborate decahydrate"). Several commercially available forms (e.g., "boron amino acid chelate," "boron ascorbate," "boron aspartate," "boron chelate," "boron citrate," "boron gluconate," "boron glycerborate," "boron glycinate," "boron picolinate," "boron proteinate," "boron bonded with niacin," and "calcium fructoborate") are not well characterized in the scientific literature. Most often, dietary boron supplements are provided in conjunction with other nutrient supplements.

BIOAVAILABILITY, EXCRETION, AND HOMEOSTASIS

If plant and animal boron absorption mechanisms are analogous, the organic forms of the element *per se* are probably unavailable (32). However, the strong association between boron and polyhydroxyl ligands (described later) is easily and rapidly reversed by dialysis, change in pH, heat, or the excess addition of another low-molecular polyhydroxyl ligand (27). Thus, within the intestinal tract, most ingested boron is probably converted to orthoboric acid (common name: boric acid), $B(OH)_3$, the normal end product of hydrolysis of most boron compounds (7). Gastrointestinal absorption of inorganic boron and subsequent urinary excretion (33) is near 100%.

Several lines of evidence suggest regulation of boron in humans. For example, lack of boron accumulation and relatively small changes in blood boron values during a substantial increase in dietary boron support the concept of boron homeostasis (33). Boron contents in human milks

Figure 8 Model and mean (\pm SE) concentrations of boron in breast milk from mothers of full-term (FT) and premature (PRT) infants; $n = 9$ per group over 12 weeks after birth. During the first 12 weeks of lactation, prematurity affected the rate of change in concentrations ($P = 0.01$).

were similar and stable throughout lactation of full-term infants in two cohorts of women living in either Houston, TX (34), or St. John's, Newfoundland (Fig. 8) (35), have been interpreted as suggestive of regulatory mechanisms for the elements, which remain undefined. Evidence for the homeostatic control of boron is enhanced further by a report (36) of a specific borate transporter, NaBC1, in mammalian cell lines, a finding that has yet to be confirmed by another laboratory.

DIETARY BORON SOURCES AND INTAKES

Dietary Recommendations

The tolerable upper intake level (UIL) for boron varies by life stage (Table 1) (37). No estimated average requirement, recommended dietary allowance, or adequate intake has been established for boron for any age–sex group.

Dietary Supplements

For adults, the amount of boron commonly provided in a single dietary boron supplement is 0.15 mg (31). However, the reported amount of boron available per serving varies considerably among commercially available products as indicated in the relevant information provided by

Table 1 Upper Limits for Boron Set by the 2001 Food and Nutrition Board of the National Academy of Sciences (37)

Life stage	Age (yr)	Upper limit (mg/day)
Children	1–3	3
	4–8	6
	9–13	11
Adolescents	14–18	17
Adults	19–70	20
	70	20
Pregnancy	≤ 18	17
	19–50	20
Lactation	≤ 18	17
	19–50	20

various dietary supplement manufacturers. Some manufacturers publish reported values of 6.0 mg boron per serving of dietary supplement (38). The mean of usual intake of boron (mg/day) from dietary supplements for children (1–8 years), adolescents (9–15 years), males (19+ years), females (19+ years), and pregnant/lactating women is 0.269, 0.160, 0.174, 0.178, and 0.148, respectively. The median boron intake from supplements in the U.S. population is approximately 0.135 mg/day (37).

Nonfood Personal Care Products

Boron is a notable contaminant or ingredient of many nonfood personal care products. For example, an antacid was reported to have a high concentration of boron (34.7 µg/g) (39) such that the maximum recommended daily dose would provide 2.0 mg B/day, two times the estimated daily boron consumption for the overall adult U.S. population.

Dietary Sources and Intakes

Ten representative foods with the highest boron concentrations are distributed among several food categories (40): raw avocado (14.3 µg/g), creamy peanut butter (5.87 µg/g); salted dry roasted peanuts (5.83 µg/g), dry roasted pecans (2.64 µg/g), bottled prune juice (5.64 µg/g), canned grape juice (3.42 µg/g), sweetened chocolate powder (4.29 µg/g), table wine (12.2% alcohol) (3.64 µg/g), prunes with tapioca (3.59 µg/g), and granola with raisins (3.55 µg/g). Several fruit, bean, pea, and nut products contained more than 2 µg B/g. Foods derived from meat, poultry, or fish have relatively low concentrations of boron.

Infant foods supply 47% of boron (B) intake to infants. For toddlers, consumption from fruits and fruit juices, combined, is twice that from milk/cheese (38% vs. 19%). For adolescents, milk/cheese foods are the single largest source of boron (18–20%), and for adults and senior citizens, it is beverages (mainly represented by instant regular coffee) (21–26%). For all groups (except infants), 7% to 21% of boron intake is contributed by each of the vegetable, fruit, and fruit drink products. Infants, toddlers, adolescent girls and boys, adult women and men, and senior women and men are estimated to consume the following amounts of boron: 0.55, 0.54, 0.59, 0.85, 0.70, 0.91, 0.73, and 0.86 mg/day, respectively.

INDICATIONS AND USAGE

Boron and Calcium Metabolism and Bone Structure

There are several lines of evidence that dietary boron is important for normal bone growth and function. Boron deprivation induced abnormal limb development in frogs (41) and retarded maturation of the growth plate in chicks (42). Dietary boron deprivation decreases bone strength in pigs (43) and rats (44). The trabecular microarchitecture of vertebral bone was impaired in rats deprived of the element (44). Similarly, in mice, modeling and remodeling of alveolar bone (45), as well as alveolar bone healing after experimental tooth extraction (46), was impaired by dietary boron deprivation.

Findings from human studies suggest that boron influences calcium metabolism. For example, in post-

menopausal women, boron supplementation (3 mg/day) of a low-boron diet (0.36 mg B/day) resulted in a 5% increase in urinary calcium excretion (33). A similar phenomenon occurred in either free-living sedentary or athletic premenopausal women consuming self-selected typical Western diets: boron supplementation increased urinary calcium loss (47). These findings may reflect an increase in intestinal calcium absorption because increase in dietary calcium often result in increased urinary calcium excretion.

Dietary boron also alleviates the signs of marginal vitamin D deficiency relevant to bone structure and function. Marginal vitamin D deficiency impairs bone structure, elevates plasma alkaline phosphatase concentrations, and reduces body weight. In the growing rachitic chick, dietary boron substantially alleviated the perturbed histomorphometric indices of bone growth cartilage (42,48), reduced elevated serum concentrations of alkaline phosphatase (49,50), and improved body weight (50,51).

Boron and Insulin and Energy Substrate Metabolism

Circulating insulin concentrations respond to dietary boron in a manner that suggests the element may function to reduce the amount of insulin needed to maintain glucose levels. For example, in the rat model (with overnight fasting), boron deprivation increased plasma insulin with no concurrent change in glucose concentrations (52). In the chick model, boron deprivation increased *in situ* peak pancreatic insulin release (52). In older volunteers (men and women) fed a low-magnesium, marginal copper diet, dietary boron deprivation induced a modest but significant increase in fasting serum glucose concentrations (53).

Findings from several studies indicate that dietary boron may attenuate the deleterious effects of marginal vitamin D deficiency on insulin and energy substrate metabolism. In vitamin D–deprived rats, hyperinsulinemia was decreased by dietary boron (54). It has been demonstrated repeatedly in the chick model that physiological amounts of dietary boron can attenuate the rise in plasma glucose concentration induced by vitamin D deficiency (42,48,55). In addition, boron decreases the abnormally elevated plasma concentrations of pyruvate, β-hydroxybutyrate, and triglycerides that are typically associated with this inadequacy (42). It is not understood how boron deprivation perturbs energy substrate metabolism in humans and animal models, particularly when other nutrients are provided in suboptimal amounts.

Boron and Immune Function

Dietary boron may have a role in control of the normal inflammatory response, especially as it relates to production of various cytokines. Cytokines, including interferon-γ (IFN-γ), tumor necrosis factor-α (TNF-α), and interleukin-6 (IL-6), are produced and secreted by immune cells that regulate immune responses. Production of IFN-γ and TNF-α was increased in peripheral blood monocytes cultured in the presence of lipopolysaccharide (an inflammatory agent) after isolation from pigs fed supplemental dietary boron. In the same animals, boron caused a reduction in localized inflammation following a challenge with

the antigen phytohemagglutinin (PHA) (56). In cell culture studies with human fibroblasts (57) and chick embryo cartilage (58), the addition of boric acid also increased TNF- α release by the respective cells. Certain boron-containing RG-II s from *Panax ginseng* leaves enhanced the expression of IL-6-producing activity of mouse macrophages (59). Finally, perimenopausal women who excreted <1.0 mg B/day during the placebo period exhibited an increased percentage of polymorphonuclear leukocytes during the boron (as sodium borate) supplementation period (60). Dietary boron may serve as a signal suppressor that down-regulates specific enzymatic activities typically elevated during inflammation at the inflammation site. Suppression, but not elimination, of these enzyme activities by boron is hypothesized to reduce the incidence and severity of inflammatory disease.

Boron and Steroid Metabolism

There is a clear evidence that dietary boron affects steroid metabolism. In particular, circulating concentrations of vitamin D metabolites are sensitive to boron nutriture. Findings from animal models indicate that dietary boron enhances the efficacy of vitamin D but cannot substitute for the vitamin. In volunteers (men, and women on or not on estrogen therapy), boron supplementation after consumption of a low-boron diet increased serum 25-hydroxycholecalciferol concentrations (62.4 ± 7.5 vs. 44.9 ± 2.5 mmol/L; mean \pm SEM) (61,62), an effect that may be especially important during the winter months when these concentrations normally range between 35 and 105 mmol/L (63).

The circulating concentrations of 17β -estradiol also respond to boron nutriture. Perimenopausal women who excreted <1.0 mg B/day during the placebo period exhibited increased serum concentrations of estradiol after boron supplementation (2.5 mg B/day) of self-selected diets (60). In a separate study, postmenopausal women on estrogen therapy, but neither men nor postmenopausal women not ingesting estrogen, also exhibited increased serum concentrations of estradiol after boron supplementation (3 mg B/day) of a low-boron diet (0.25 mg B/2000 kcal) (62). However, plasma estradiol, but not testosterone, concentrations increased in young male volunteers when their self-selected diets were supplemented with ample amounts of boron (10 mg/day) (64).

Boron and Cancer

Indirect evidence from several epidemiological and cell culture studies indicate that dietary boron intake may affect cancer risk. For example, observations from epidemiologic human studies suggest that increased intakes of boron are associated with decreased risk of prostate (65) and lung (66) cancers and abnormal cervical cytopathology (67). In cultures of human prostatic epithelial cells (not tested for proliferative activity), physiological levels of boron reduced Ca^{2+} release from ryanodine receptor-sensitive stores in a dose-dependent manner, without affecting cytoplasmic Ca^{2+} concentrations (68). In immunocompromised mice fed physiological amounts of dietary boron, the element reduced the growth of transplanted human prostate adenocarcinoma tumors (69).

OVERDOSAGE

As with all other elements, boron produces toxicity in all tested biological organisms when excessive amounts are absorbed. The toxicity signs associated with boric acid when used as an antiseptic in lieu of antibiotics on abraded epithelium (i.e., surgical wounds and diaper rash) were overlooked for many years even though signs of poisoning were reported soon after its introduction into clinical use. Boron is more bacteriostatic than does bactericidal and, thus, may suppress bacterial growth.

Deaths can occur at doses between 5 and 20 g of boric acid for adults and below 5 g total for infants (70,71). Potential lethal doses are usually cited as 3 to 6 g total for infants and 15 to 20 g total for adults. However, an independent examination of 784 cases of boric acid ingestion found minimal or no toxicity at these intake levels or higher (72). Signs of acute boron toxicity, regardless of route of administration, include nausea, vomiting, headache, diarrhea, erythema, hypothermia, restlessness, weariness, desquamation, renal injury, and death from circulatory collapse and shock. Autopsy may reveal congestion and edema of brain, myocardium, lungs, and other organs, with fatty infiltration of the liver. Chronic heavy borax dust occupational exposure (average air concentration: 4.1 mg/m^3 ; range: $1.2\text{--}8.5 \text{ mg/m}^3$) may manifest as eye irritation, nosebleeds, chest tightness, sore throat, dry mouth, and productive cough (71). Chronic boron toxicity symptoms include poor appetite; nausea; weight loss; decreased sexual activity, seminal volume, sperm count, and motility and increased seminal fructose. At present, death from boron poisoning is exceptionally rare probably because of the emphasis placed on maintaining electrolytic balance and supporting kidney function during the worst part of the illness. Depending upon boron blood levels, treatment ranges from observation to gastric lavage to dialysis.

CONCLUSIONS

Boron is ubiquitous in the environment and daily dietary boron intakes of adult American males, for example, are slightly less than 1.0 mg. The evidence to date suggests that higher animals (43,73) and humans (33,62,74) probably require boron to support normal biological functions. Despite the progress made in studies of boron essentiality for plants, animals, and man, the biochemical mechanisms responsible for the beneficial physiologic effects of boron across the phylogenetic spectrum are poorly understood. However, the unique nature of boron biochemistry suggests specific lines of investigation. In particular, further characterization of the various cell signaling molecules that form complexes with boron under physiological conditions should provide insights into the specific biochemical function(s) of boron in humans.

Caffeine

Harris R. Lieberman, Christina E. Carvey, and Lauren A. Thompson

INTRODUCTION

Caffeine is undoubtedly one of the most widely consumed and studied dietary supplements because it is found in many products, including numerous foods and drugs. Approximately 50% of the U.S. adult population regularly uses one or more dietary supplements, but 80% or more regularly consumes caffeine. Thousands of studies have investigated this substance, and a comprehensive discussion of all aspects of the literature on caffeine would require hundreds of pages of text. Substantial literature on caffeine can be found in multiple scientific fields including pharmacology, exercise and cardiovascular physiology, psychology, psychiatry, and epidemiology (1,2).

Caffeine occurs naturally in beverages and foods, including coffee, tea, the South American drink maté, and chocolate. Additional caffeine is added to beverages, including colas, which naturally contain caffeine, because manufacturers of these products have determined that optimal levels of caffeine should be greater than their naturally occurring concentration. Caffeine is behaviorally active in the doses present in foods (3) and is the most widely consumed psychoactive substance in the world. Caffeine is recognized in scientific and regulatory domains as both a naturally occurring food and a drug, a distinction that few, if any, other substances hold.

HISTORY OF CAFFEINE USE

The first written mention of a caffeine-containing food or beverage, tea, is in a Chinese dictionary from about AD 350 (4). However, it is likely that tea was in use long before then. Coffee was cultivated in Ethiopia as early as the sixth century AD, where it originated. Coffee beans were probably first eaten whole or mixed with food (4). Coffee came into use as a hot beverage around AD 1000 in the Middle East but did not spread to Europe until the 17th century. Coffee is currently second only to water as the beverage of choice around the world, with an estimated 400 billion cups of coffee consumed each year (5). The two most common species of the coffee plant are *Coffea arabica* and *Coffea canephora* Pierre ex. A. Froehner (commonly known as robusta). Approximately two-thirds of the world's coffee comes from arabica plants, whereas one-third comes from robusta (5). Arabica coffee has a smoother and superior taste but requires extensive care in growing. Arabica

beans contain approximately 1.5% or less of caffeine by dry weight (5). Robusta beans, grown in regions such as Brazil, have a higher caffeine content, 2.4% to 2.8%, which may explain their less-preferred flavor, because caffeine itself is quite bitter (5). At least 60 species of plants contain caffeine. The reason so many plants contain caffeine is not known, but caffeine protects plants from certain insects (6).

Tea [*Camellia sinensis* (L.) Kuntze] is the caffeinated beverage of choice in a large part of the world, although it contains less caffeine than coffee (Table 1). It appears that caffeine-containing beverages originated independently in at least four different locations throughout the world. In both North and South America, caffeine-containing beverages were made by the native inhabitants prior to contact with Europe. The sources of caffeine in North America were the cassina or Christmas berry tree (*Ilex vomitoria* Ait.) and in South America guarana (*Paullinia cupana* Kunth) and yoco (4). Caffeine is present in cocoa beans (*Theobroma cacao* L.), native to Central and South America. A compound chemically similar to caffeine, theobromine, is also found in cocoa but in substantially greater amounts than caffeine. Although the popularity of caffeine is widely recognized, the rationale for its unique status in the diets of humans is not known, but many have speculated its mild stimulant properties account for its popularity.

PHARMACOLOGY OF CAFFEINE

Caffeine is a methylated xanthine, 1,3,7-trimethylxanthine; theophylline and theobromine are two other methylated xanthines found in foods and/or drugs (Fig. 1). Theobromine, 3,7-dimethylxanthine, is not behaviorally active in doses found in foods (7). Theophylline, 1,3-dimethylxanthine, used to treat asthma, is not present in coffee but found in small quantities in tea (*C. sinensis*). The parent compound of these methylated compounds is xanthine, a dioxypurine structurally similar to uric acid (8).

When ingested, caffeine is rapidly absorbed into the systemic circulation and reaches peak levels in 45 minutes or less (9). Caffeine is distributed to all tissues and readily crosses the blood-brain barrier, which explains its behavioral activity. Caffeine is initially absorbed by the buccal membranes (in the mouth) and, when consumed in chewing gum, enters the circulatory system more rapidly than when ingested in pill form (10).

Table 1 Estimated Caffeine Content of Selected Beverages, Foods, and Dietary Supplements (32) (Energyfiend.com; Evitamins.com)

Item	Caffeine content (mg/serving)
Coffee (5 oz)	
Drip method	90–150
Instant	40–108
Decaffeinated	2–5
Tea, loose or bags	
1-minute brew (5 oz)	9–33
5-minute brew (5 oz)	20–50
Iced tea (12 oz)	22–36
Chocolate products	
Hot cocoa (6 oz)	2–8
Chocolate milk (8 oz)	2–7
Milk chocolate (1 oz)	1–15
Baking chocolate (1 oz)	35
Cola beverages (12 oz)	
Coca-Cola® Classic	35
Diet Coke®	47
Pepsi®	38
Diet Pepsi®	36
Other Soft drinks (12 oz)	
Dr Pepper®	40
Mountain Dew®	55

CAFFEINE METABOLISM

The period of time caffeine remains in the circulatory system, measured as half-life, varies dramatically. Half-life of caffeine in a healthy adult is approximately four to five hours, but in women taking oral contraceptives, it can increase substantially. In cigarette smokers, caffeine is metabolized more rapidly and has a half-life of about three hours (11,12).

Caffeine is metabolized in the liver by a complex series of processes. The principal metabolic pathway, which accounts for approximately 95% of initial breakdown of caffeine, is catalyzed by the cytochrome P450 enzyme CYP1A2 (13). The process begins with removal of a methyl

**Figure 1** Chemical structures of caffeine, its demethylated derivatives (theobromine, theophylline, paraxanthine), its parent compound (xanthine), and uric acid.

group to form paraxanthine and, to a lesser extent, theobromine and theophylline (Fig. 2).

Various factors alter CYP1A2 activity. For example, both pregnancy and severe liver disease result in decreased caffeine clearance (13,14). Conversely, smoking induces CYP1A2 activity, thereby decreasing half-life of caffeine (14). Many pharmacologic substances also affect this enzyme: oral contraceptives and cimetidine inhibit the enzyme and slow caffeine clearance (14), whereas other drugs (e.g., phenytoin, carbamazepine) induce the enzyme, accelerating caffeine metabolism.

Dietary practices influence CYP1A2 activity. Caffeine intake itself induces this enzyme, so heavy consumers metabolize caffeine more rapidly (15), explaining, in part, why they are less sensitive to its behavioral and physiological effects. Cruciferous vegetables (e.g., broccoli, kale, turnip) increase CYP1A2 activity, whereas apicomplex vegetables (e.g., cilantro, parsnip, celery) inhibit it (16).

Genetic Differences in Caffeine Metabolism

Genetic variation is partly responsible for different phenotypes of caffeine metabolism (17). Several CYP1A2 single nucleotide polymorphisms (SNPs) have been characterized (18). One, CYP1A2*1F, is a substitution (A → C) at position 734 on the CYP1A2 gene. Approximately 10% to 16% of individuals have the CYP1A2 C/C (homozygous) genotype, whereas about half possess two A alleles (18). Individuals with the CYP1A2*1F A → C polymorphism are slower to metabolize caffeine and less likely to increase CYP1A2 activity following exposure to inducers. There may be physiological consequences of genetic differences in caffeine metabolism. For example, a recent study linked the slow-metabolizing CYP1A2*1F C/C genotype, with increased risk of heart disease associated with coffee consumption (19).

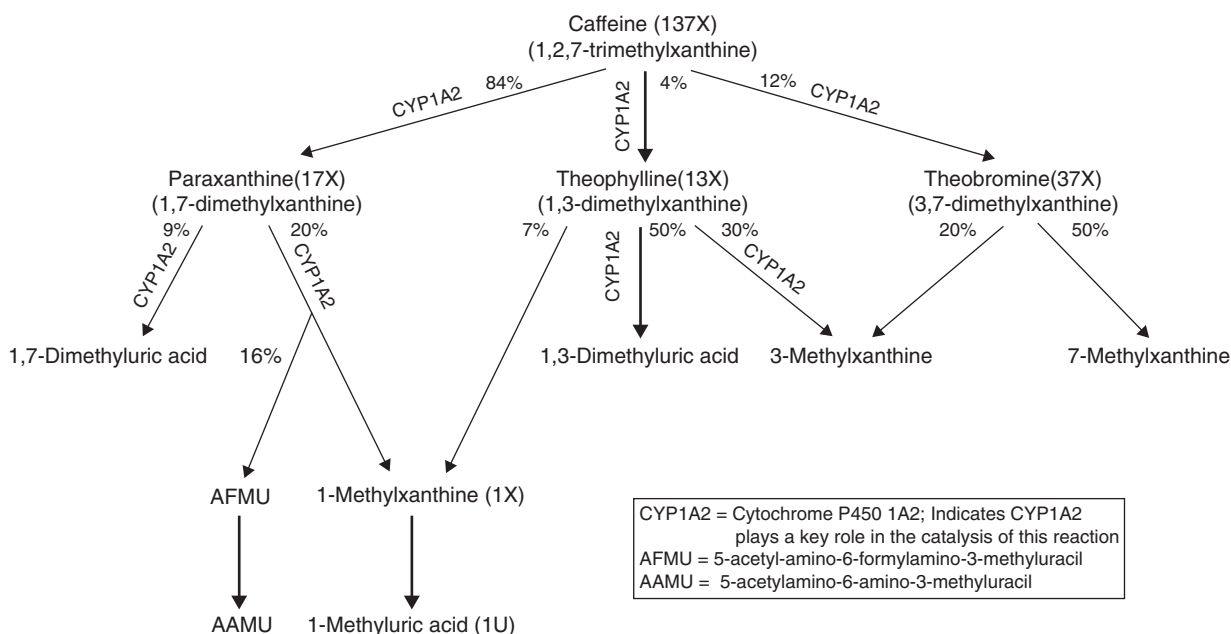

Figure 2 Metabolic pathways of caffeine and its derivatives. Only pathways that begin with N-demethylation are shown, which account for almost 95% of initial breakdown. Less than 3% of caffeine is excreted unchanged in the urine; the remainder is metabolized to 1,3,7-trimethyl uric acid (not shown). Source: From Ref. 17.

MECHANISM OF ACTION

Caffeine's behavioral, as well as ergogenic effects can be attributed to central adenosine receptors (20,21). Adenosine is an inhibitory neuromodulator in the central nervous system that has sedative-like properties. Under normal physiological conditions, caffeine is a nonselective competitive antagonist at these receptors. Four subtypes, A_1 , A_{2a} , A_{2b} , and A_3 , of G-protein-coupled adenosine receptors have been identified, each with a unique tissue distribution, signaling pathway, and pharmacological profile (22,23). Through the respective activation of G_i and G_s proteins, adenosine decreases adenylate cyclase activity, and hence, cAMP levels, when bound to A_1 or A_3 receptors, and increases activity when bound to A_{2a} or A_{2b} receptors (22,23).

Prior to discovery of caffeine's action on adenosine receptors, effects of caffeine were attributed to inhibition of phosphodiesterase (PDE) (24). However, the concentration of caffeine required to inhibit PDE substantially exceeds that achieved from consumption of caffeine in foods or dietary supplements. While caffeine blocks A_1 and A_{2a} receptors at concentrations in the low micromolar range (5–30 μ M), approximately 20 times as much caffeine is required to inhibit PDE, well above physiological levels as illustrated in Figure 3, which also presents the approximate caffeine concentration from consumption of a cup of coffee (25,26).

All four adenosine receptor subtypes are expressed to various extents in the brain and periphery (23). Adenosine A_1 receptors are widely distributed in the periphery, spinal cord, and brain, with high levels found in hippocampus, cortex, cerebellum, and hypothalamic nuclei; lower levels of the A_1 subtype are found in the basal

Figure 3 Concentration-effect curves for caffeine at various potential sites of action. Caffeine markedly affects A_1 and A_{2a} receptors at low micromolar concentrations. To inhibit phosphodiesterase (PDE), concentrations as large as 20-times are required. Approximate caffeine concentration resulting from a single cup of coffee and toxic doses of caffeine is indicated. Source: From Ref. 26.

ganglia (23). The A_{2a}, A_{2b}, and A₃ receptors are mainly expressed in the periphery; however, there is marked expression of the A_{2a} receptors in regions heavily innervated by dopamine-containing fibers, including the striatum, nucleus accumbens, and olfactory tubercle, where they are coexpressed with dopamine D₂ receptors (27).

Caffeine binds with highest affinity at A_{2a} receptor and has slightly lower affinity at the A₁ and the A_{2b} receptors; the A₃ subtype has little to no affinity (24). At standard physiological concentrations (i.e., low micromolar), effects of caffeine are due to blockade at A₁ and A_{2a} receptors, with binding at A_{2b} and A₃ receptors having a minor role, if any (22,27).

Both adenosine A₁ and A_{2a} receptors may be responsible for behavioral effects of caffeine, but the contribution of each is uncertain. The A₁ receptors are located predominantly on presynaptic nerve terminals and mediate release of several neurotransmitters, including glutamate, dopamine, and acetylcholine. Caffeine is thought to enhance arousal, vigilance, and attention by blocking inhibition by adenosine at these receptors, particularly those in the striatum (22). Caffeine may stimulate arousal via A₁ receptors by preventing inhibition of mesopontine cholinergic neurons that regulate cortical activity and arousal (22).

Unlike dopaminergic stimulants, such as cocaine and amphetamine, which facilitate dopamine D₂ receptor transmission, caffeine does not alter dopamine release in ventral striatum (22). This may explain why caffeine does not have the abuse potential of these stimulants.

Genetic Differences in Adenosine Receptors

Recently, it was shown in humans that a particular polymorphism (a T→C substitution at position 1976; also known as SNP rs5751876 or 1976T→C, and formerly known as 1083T→C) of the A_{2a} receptor gene (*ADORA2A*) is associated with effects of caffeine on sleep (28). It appears that 16% of individuals are homozygous for the T allele and roughly 35% are homozygous for the C allele (29). While inhibition of A₁ receptors may be partly responsible for wakefulness promoted by caffeine, most evidence suggests caffeine-induced arousal is due to blockade at A_{2a} receptors (23).

Individuals with the *ADORA2A* C/C genotype are more likely to report disturbed sleep following caffeine consumption compared with individuals with the T/T genotype (28). Consistent with these genetic differences, associations were observed between self-reported caffeine-sensitivity, assessed by questionnaire, and *ADORA2A* genotype. A higher proportion of sensitive subjects had the C/C genotype, whereas the T/T genotype was more frequent in insensitive subjects (28). In a sleep deprivation study conducted in a subset of the survey population, caffeine-sensitive men reported greater stimulant-like effects of caffeine compared with those who were caffeine-insensitive. In addition, ratings of caffeine sensitivity were positively correlated with psychomotor vigilance after sleep loss (28). Also, the C allele is associated with caffeine-induced insomnia, and the T allele appears to be related to caffeine-induced anxiety. Infrequent caffeine users consuming less than 300 mg/wk, who possess the *ADORA2A* 1976T/T genotype, experienced

greater anxiety following 150 mg caffeine compared with those who possessed at least one C allele (29). Individuals with the T/T genotype are significantly more likely to limit caffeine intake (i.e., consume <100 mg/day) than those who possess at least one C allele, with the probability of having the T/T genotype decreasing as caffeine intake increases (30).

CAFFEINE CONTENT OF VARIOUS PRODUCTS

In the United States, most of caffeine (approximately 80%) is consumed in coffee (31). Caffeine is also found in soft drinks, especially colas, energy drinks, tea, chocolate, over-the-counter (OTC) drugs, and dietary supplements (Table 1) (32). Some non-cola beverages also contain caffeine such as Mountain Dew[®], Dr Pepper[®], and Pibb Xtra[®]. There is tremendous variation in the caffeine in a cup of coffee. Instant coffee (5 oz) can have as little as 40 mg of caffeine, whereas drip-method brewed coffee can have as much as 150 mg (Table 1). There is considerable variation in coffee prepared using the same method, due to differences in caffeine content of different types of coffee beans, especially arabica versus robusta, and variations in brewing technique.

CAFFEINE INTAKE

Recent information on caffeine consumption in the United States is not available. The most current data are based on information collected between 1994–1998 (33) and 1999 (34). Using data from the nationally representative U.S. Department of Agriculture Continuing Survey of Food Intakes by Individuals ($n = 18,081$), Frary et al. reported, in 1994–1998, that 87% of the population was caffeine consumers, with an average caffeine intake of 193 mg/day in users. Adult males consumed more caffeine than females (268 mg/day vs. 192 mg/day). Coffee was the major source of caffeine for consumers of all ages (68 mg/day), followed by 15 mg/day from soft drinks and 12 mg/day from tea (33). However, Ahuja et al. (35) concluded that Frary et al. overestimated caffeine intake and revised their estimates downward by about 25%. According to Ahuja et al., average daily intake of caffeine in the U.S. population is 131 mg/day, with males and females (20+ years) consuming 193 and 149 mg/day, respectively (35). Knight et al. (34) estimated caffeine intake in caffeine consumers ($n = 10,712$) from beverages on the basis of data from the 1999 U.S. Share of Intake Panel as 141 mg/day for adults. There are other reports of higher caffeine consumption in the United States. Barone and Roberts (31) reported that U.S. caffeine intake for all consumers is about 210 mg/day.

Since these data were collected, changes in availability of caffeine-containing products have occurred and consumer preferences have changed (36). Energy drinks, introduced in the United States in 1997, contain caffeine (Table 1) and are a popular component of the diet, especially among young adults (36). Another new product containing high levels of caffeine (Table 1) termed “energy shots” is rapidly gaining in popularity.

High levels of caffeine are present in many dietary supplements (Table 1), particularly those intended to promote weight loss, for example, Zantrex 3[®] and new Hydroxycut Advanced[™] (37–39). Unfortunately, manufacturers of such products are not required to disclose their caffeine content, so this information can be difficult to obtain. These products have not been shown to increase weight loss, and recently some of the Hydroxycut[™] family of products was withdrawn from the market after the FDA issued a warning (40).

REGULATORY STATUS OF CAFFEINE

In the United States, complex regulations govern use of caffeine. Once caffeine is ingested and enters circulation, its source is of little physiological or health significance, but U.S. government agencies, in practice, regulate it on the basis of the medium in which it is consumed. Caffeine consumed in dietary supplements, occurring naturally in foods, caffeine added to foods, and caffeine in OTC and prescription drugs are all regulated differently. Multiple sources of caffeine ingestion and regulation can lead to peculiar consequences. For example, a large cup of coffee purchased at a coffee shop can contain more caffeine than the recommended dose of an OTC stimulant. The recent popularity of energy drinks has led to calls for additional regulation of such products, because it has been argued that these products are abused (36).

BEHAVIORAL EFFECTS OF CAFFEINE

It is likely that caffeine is the most widely studied behaviorally active compound not only in dietary supplements, but also in any exogenously administered compound. Caffeine's behavioral effects have been examined in a large number of laboratories and in well-controlled studies conducted with males, females, young, and older volunteers (41–43). Effects observed on specific aspects of cognitive function and mood state are usually consistent with the lay

perception of caffeine as a mild stimulant when consumed in moderate doses, just as Pietro della Valle recognized 400 years ago (44).

However, it can be difficult to detect effects of caffeine if insensitive behavioral tests that assess parameters not affected by caffeine are employed or doses that are too low or high administered. In addition, it is essential to control intake of caffeine before testing and monitor and control for habitual patterns of caffeine consumption, as these factors can have substantial effects on study findings. Controlling for tobacco use is also essential, because smoking significantly decreases caffeine's half-life. Furthermore, well-designed studies typically employ a range of doses, since caffeine's behavioral effects are dose dependent and nonmonotonic.

Effects on Cognitive Performance and Mood in Rested Volunteers

In rested volunteers, caffeine consistently improves both auditory and visual vigilance (3,41,45–48). When a dose of 200 mg of caffeine is given, effects on vigilance are seen for several hours and are so robust that they can be detected on a minute-by-minute basis (45) (Fig. 4). Such effects are present with doses equivalent to a single serving of a cola beverage, about 40 mg, up to multiple cups of coffee (3,43,46). However, when higher doses are administered (approximately 400–500 mg or above), cognitive performance begins to deteriorate, so optimal dose appears to be in the range found in foods (49,50). Caffeine also improves simple and choice reaction time in rested individuals (51). In general, it appears that sustained tests of vigilance or tasks with substantial embedded vigilance components are the most sensitive to behavioral effects of caffeine in rested individuals.

Mood state is also altered by doses of caffeine equivalent to those found in single and multiple servings of dietary supplements, foods, and drugs. Aspects of mood affected by caffeine are consistent with its effects on cognitive functions such as vigilance and reaction time. For example, the vigor and fatigue subscales of the Profile of Mood States (POMS) (52), a widely used self-report mood

Figure 4 Effect of a 200-mg caffeine dose administered at time "0" on visual vigilance reaction time assessed continuously and plotted in 10 minute time blocks. Slower reaction time (higher number) indicates worse performance ($p < 0.002$; caffeine vs. placebo). Caffeine consistently improved cognitive performance for two hours. Source: From Ref. 45.

Figure 5 Effects of 64 to 256 mg of caffeine compared to placebo (mean \pm SEM) on the fatigue and vigor subscales of the Profile of Mood States (POMS). Difference scores were computed by subtracting the baseline from posttreatment values. Higher numbers on the vigor subscale indicate increased vigor; lower numbers on the fatigue subscale indicate lowered fatigue. * $p < 0.05$ caffeine vs. placebo Source: From Ref. 32.

questionnaire, are altered by caffeine in a dose-dependent manner (Fig. 5). Caffeine typically increases vigor and reduces fatigue. At higher doses, these beneficial effects may be reduced or disappear. An analog scale mood questionnaire designed to assess effects of caffeine consistently detects effects on moods such as tired/energetic, listless/full of go, and efficient/inefficient (41).

Fine Motor Performance

Caffeine consumption has been associated, at least anecdotally, with impaired fine motor performance. When administered in a dose of 160 mg, it disrupted hand steadiness in nonusers but not in users (53). In a study with low and moderate consumers, doses of 32 to 256 mg of caffeine

had no effect on tests of complex motor function (54). A recent study examined effect of caffeine on handwriting in caffeine consumers (54). In this study, subjects were administered caffeine in doses of 0, 1.5, 3.0, or 4.5 mg/kg and performed a writing exercise on a digitized tablet. Compared to placebo, high doses of caffeine improved aspects of handwriting, such as fluidity of movement (54). Caffeine has also been reported to improve marksmanship, a task that requires fine motor performance (55).

Caffeine and Anxiety

It appears that caffeine increases anxiety when administered in single bolus doses of 300 mg or higher, a dose not ordinarily found in single servings of beverages, although there are some exceptions. Generally, large servings of beverages, such as 16 oz of coffee, that contain high amounts of caffeine, are consumed slowly over time. Some products, for example certain brands of energy drinks or energy shots, do contain such high levels of caffeine and may be consumed quickly, especially energy shots (Table 1). The effects of caffeine on anxiety at lower doses are unclear, with both positive and adverse effects reported, perhaps due to differences in the testing environment (50,56).

Several papers suggest caffeine consumption can adversely affect individuals suffering from anxiety disorders. Also, consumption of more than 600 mg of caffeine per day may induce, in normal individuals, a syndrome known as "caffeinism," characterized by anxiety, disturbed sleep, and psychophysiological complaints (57).

Effects on Cognitive Performance and Mood During Sleep-Deprivation and Stress

Caffeine has substantial beneficial effects on cognitive performance and mood when individuals are sleep deprived or exposed to multiple stressors (50,58,59). Under such conditions, caffeine positively affects various behavioral parameters, including vigilance and mood state. For example, during a night of sleep deprivation, 200 mg of caffeine administered every two hours maintained vigilance performance (60). Other behavioral parameters, such as learning, memory, and reasoning, not altered when caffeine is administered to rested volunteers, are affected when individuals are sleep-deprived (50). When individuals were sleep-deprived for 30 hours but not exposed to additional stressors, 300 mg of caffeine per 70 kg of body mass improved working memory, logical reasoning, mathematical processing, pursuit tracking, and visual vigilance (61). In a study conducted with U.S. Navy SEAL trainees exposed to multiple stressors including cold, intense physical challenges, 72 hours of sleep deprivation, and severe psychological stress, caffeine in doses of 200 and 300 mg improved visual vigilance, choice reaction time, and self-reported alertness (50) (Fig. 6).

Simulator and Applied Behavioral Studies

Based, in part, on studies demonstrating caffeine has beneficial effects in laboratory studies of cognitive performance and mood, studies have been conducted to determine whether caffeine will have beneficial effects in simulated or real work environments. For example, Regina et al. (6) tested rested males in a realistic simulation

Figure 6 U.S. Navy SEAL trainees are exposed to multiple stressors during a segment of training known colloquially as “Hell Week.” This provided a unique opportunity to test the behavioral effects of caffeine during sustained exposure to severe stress (50). Cold stress serves as a key physiological stressor during most of Hell Week. As instructors look on, trainees are required to walk into the cold ocean water. Source: Photo courtesy of H.R. Lieberman.

of highway driving. Caffeine (200 mg) improved several aspects of driving performance including response time to accelerations and decelerations of a lead car. Philip et al. (63) examined effects of approximately 200 mg of caffeine administered in coffee on rested, young male volunteers driving a distance of 200 km late at night on a highway. Caffeine improved ability to maintain control of the vehicle as measured by deviation from the traffic lane. In a study simulating sentry duty, Johnson and Merullo (64) evaluated the effects of 200 mg of caffeine on marksmanship for three hours following caffeine administration. Soldiers in the study responded to infrequent appearance of a target by picking up a rifle, aiming, and firing as rapidly, and accurately, as possible. Caffeine decreased detection time but did not increase the number of targets hit.

Recently, a series of studies have been conducted by Kamimori and colleagues using a caffeine-containing gum to determine whether caffeine would enhance performance under conditions simulating combat, including intermittent or continuous sleep deprivation and extensive physical activity. These studies uniformly demonstrate that in a wide variety of circumstances, various aspects of cognitive, operational, and aerobic performance are enhanced by caffeine (58,59).

In aggregate, these behavioral studies have important practical implications. Use of caffeine in moderate doses can improve the performance of individuals who must drive automobiles or stand sentry duty for long periods of time during the day or night. These beneficial effects increase in situations where vigilance is reduced due to sleep loss, jet lag, or circadian variations in arousal. Recently, at the request of the U.S. Defense Department, an independent panel conducted a comprehensive review of the scientific literature and concluded that caffeine, in doses of 100 to 600 mg, could be used to maintain cognitive performance of military personnel. As a consequence, caffeine is currently available in certain field rations (2,65).

CAFFEINE AND MENTAL ENERGY

Considerable attention has focused on dietary supplements and foods that may increase “mental energy,” and most of these contain caffeine. As noted above, new product categories of “energy drinks” and “energy shots” have emerged as popular products among the population (36). Scientific literature on mental energy is quite limited (66–68), although related factors, such as fatigue and alertness, have been extensively examined. Scientists have typically used the term “energy” to describe the concept of physical energy measured in calories or joules. Mental energy, however, cannot be easily defined or measured, but a distinction between physical and mental energy clearly exists (32,68–70).

In the United States, surveys have observed a high prevalence of feelings of low energy. For the lay public, mental energy is perceived as critical for the conduct of daily activities and quality of life. On health-related Internet sites, “fatigue,” “tiredness,” or “absence of energy” are among the largest concerns for which remedies are sought. To address consumer demand for such products, dietary supplements and foods containing caffeine have been marketed asserting they enhance energy (36,69). Some have been evaluated by use of cognitive tests, and the results are usually consistent with the claims made (68).

Caffeine is one of the few constituents found in dietary supplements or foods that clearly increase mental energy (32,68). As noted above, low and moderate doses improve aspects of cognitive performance and mood associated with the perception of mental energy such as vigilance, reaction time, vigor, and fatigue (68,71). Beneficial effects of caffeine that appear related to mental energy are observed in simulations of real-world activities (58,59,62,64,72). Caffeine (100 mg) increases alertness and self-reported attention in college students attending a lecture (56). Epidemiological studies of large populations indicate caffeine consumption has positive effects on factors related to mental energy in large populations (73). In a sample of over 7000 British adults, a significant dose-response relationship between increased overall caffeine intake and improved cognitive performance was observed (73). Inclusion of caffeine in products intended to increase perception of mental energy therefore appears warranted. Caffeine may be the only active ingredient in such products, if mental as opposed to physical energy is the implied benefit (32,68).

EFFECTS OF CAFFEINE ON SLEEP

It is not surprising that caffeine may interfere with sleep, because it improves ability to sustain vigilance and increases alertness. Many individuals abstain from caffeine consumption in the afternoon and evening because they believe caffeine will disrupt nighttime sleep. Others report they consume caffeine-containing beverages before bedtime with no adverse impact on sleep (74). Genetic differences in sensitivity to caffeine, as discussed above, and acquired tolerance by individuals who consume caffeine, probably contribute to these differences. Consumers of 3 to 6 cups of coffee per day are less likely to report sleep

disturbances than individuals who consume 0 to 1 cups per day (74).

Anecdotal reports that caffeine interferes with sleep are supported by the scientific literature. In both high and low consumers, a high dose of caffeine (4.0 mg/kg) at bedtime reduced sleep tendency, as measured by the Multiple Sleep Latency test (75). A recent study examined effects of moderate doses of caffeine before bedtime on various sleep parameters assessed with polysomnography. Subjects received 100 mg of caffeine (or placebo) three hours and then one hour before sleeping in the laboratory. Caffeine lengthened sleep latency, increased stage 1 sleep (light sleep) and reduced slow-wave and stage 2 sleep (deeper sleep) (76).

BEHAVIORAL EFFECTS OF CAFFEINE: NONUSERS AND WITHDRAWAL

One of the most controversial issues regarding the behavioral effects of caffeine is whether it affects performance and mood independent of withdrawal symptoms. It has been suggested that behavioral effects of caffeine can only be observed in habituated individuals experiencing effects of caffeine withdrawal on performance and mood when treated with placebo (77). If this hypothesis is correct then caffeine should have no effects on individuals who are not regular users. Several studies that fail to find behavioral effects of caffeine in individuals who are not habitual users support this hypothesis (77,78). However, there are several problems with this hypothesis and the experimental evidence supporting it. No plausible mechanism has been advanced to explain how a substance could have no acute effects on cognitive function, yet have effects when it is withdrawn. Many substances produce tolerance when administered for sustained periods. However, these substances have acute behavioral effects consistent with behavioral consequences of their withdrawal. Examples include drugs of abuse, such as heroin, and therapeutic compounds such as the benzodiazepines. To test the hypothesis advanced by Rogers and colleagues that caffeine only has behavioral effects on habitual users, a number of laboratories have conducted studies. These demonstrate caffeine has behavioral effects on nonusers and affects users who continue with their typical patterns of caffeine consumption (47,48,51).

CAFFEINE AND PHYSICAL PERFORMANCE

Just as caffeine improves specific aspects of cognitive performance and mood, it also has positive effects on some aspects of physical performance; however, it is not clear that these effects occur in doses found in most dietary supplements or foods. Evidence that caffeine enhances aerobic performance is convincing. A review of the literature concluded that "caffeine effectively increases athletic performances in endurance events" (79). For example, when 4 mg/kg of caffeine was administered to eight male volunteers, time to run to exhaustion increased (80). In another study, 3 and 6 mg/kg of caffeine enhanced endurance but a higher dose, 9 mg/kg, did not (81). Beneficial effects of caffeine assessed with a bicycle ergometer were observed

at doses 5 and 9 mg/kg, a higher dose (13 mg/kg) was no more effective than lower doses (82).

These dose-dependent findings are similar to behavioral studies with caffeine, in which higher doses can have adverse effects on mood and do not enhance performance to the same extent as moderate doses (49,50). It appears that ergogenic effects of caffeine, like caffeine's behavioral effects, are attributable to its effects on central adenosine receptors (21).

CAFFEINE WITHDRAWAL

Sudden withdrawal of caffeine from the diet, if regularly consumed in substantial doses, can have adverse effects in approximately 50% of users. Most notable is headache, which is relieved by consumption of caffeine. Onset of symptoms typically occurs in 12 to 24 hours and may last for several days. Other symptoms can include fatigue, lower energy, and difficulty concentrating. Caffeine-withdrawal headaches are relieved by OTC analgesics (83,84). Individuals who wish to reduce or eliminate caffeine from their diet should probably do so gradually.

ABUSE POTENTIAL OF CAFFEINE

Although controversial, it has been suggested that caffeine should be considered an addictive compound and is similar to drugs that have substantial abuse potential, such as nicotine and cocaine (85). Evidence for this association includes adverse physical effects of caffeine withdrawal in animals and human studies of caffeine self-administration (84). Hirsh (83) has noted that addiction can best be defined as compulsion to use a drug, and specifically, involvement with the abused substances to the exclusion of other interests. The use of methylxanthines in foods and beverages would not appear to qualify as such behavior (83). Most individuals who are regular users of caffeine can readily halt its use and not feel compelled to continue consuming caffeine-containing products. It is much more difficult to stop using drugs of abuse despite the fact that these substances are known to be extremely harmful. Caffeine clearly has low abuse potential compared to more widely recognized drugs of abuse (86).

CONCLUSION

When caffeine is consumed in doses found in foods and dietary supplements, it improves ability to perform tasks requiring sustained vigilance, including real and simulated automobile driving, and activities that require maintenance of vigilance (50,58,59). In addition, caffeine increases self-reported alertness and decreases sleepiness. Caffeine positively affects a wide range of cognitive functions in sleep-deprived individuals, including learning, memory, and reasoning. Caffeine can be found in many dietary supplements, which are marketed to increase weight loss, but evidence to support this implied claim is lacking.

Adverse behavioral effects of caffeine occur when it is consumed in excessive doses or by individuals who are more sensitive to the substance. Genetic factors and an

individual history of caffeine consumption may be the key factors explaining individual differences. In high doses, caffeine can increase anxiety but its effects on fine motor performance vary with improvement and impairment reported. It also interferes with sleep when consumed by certain individuals at bedtime. Like many other drugs, regular caffeine consumption appears to produce tolerance to its behavioral effects. Sudden withdrawal of caffeine from the diet will lead to adverse symptoms, such as headache and undesirable changes in mood state, in approximately 50% of individuals. Some scientists believe that caffeine has properties that are similar to those exhibited by drugs of abuse; others strongly disagree with this hypothesis.

An evidence-based determination of the risk-to-benefit ratio of caffeine consumption is not possible. Positive behavioral consequences of caffeine are well documented. These beneficial effects generalize to highway driving, various military duties, and presumably other transportation and industrial operations. Use of caffeine in such circumstances could potentially prevent accidents attributable to lapses of vigilance such as "falling asleep at the wheel." Such accidents are a significant cause of motor vehicle accidents. However, adverse effects of caffeine on sleep quality have been observed, and some scientists believe that caffeine has characteristics of an addictive drug.

It must also be noted that a large and complex literature on possible beneficial and adverse effects of caffeine on the incidence of various diseases exists. There are many methodological concerns with both positive and negative studies. The difficulty in accurately assessing caffeine intake is a critical issue in such studies as is the lack of double-blind, placebo-controlled clinical trials. Therefore, both positive and negative findings regarding possible health risks and benefits of caffeine should be regarded with skepticism.

Calcium

Robert P. Heaney

INTRODUCTION

Calcium is an alkaline earth, divalent, cationic element, abundant in the biosphere, and widely distributed in nature. It exhibits intermediate solubility. As a solid, calcium forms crystalline minerals with various anions. These salts make up the bulk of limestone, marble, gypsum, coral, pearls, seashells, bones, and antlers. In solution, the calcium ionic radius (0.99 Å units) allows the ion to fit snugly into the folds of protein molecules.

ACTIONS AND PHARMACOLOGY/PHYSIOLOGY

Calcium is unusual—perhaps unique—among the nutrients in that its intake (whether from foods or supplements) is not related to its primary intracellular, metabolic function. Rather, calcium nutrition is centered almost exclusively on the secondary functions of the nutrient. Accordingly, the primary functions are described here for completeness, but only briefly. More information can be found in standard textbooks of cell physiology or in reviews of calcium signaling (1).

Primary Metabolic Functions

Calcium acts as a second messenger within cells, linking external stimuli acting on cells to the specific, internal responses a cell is able to make (e.g., nerve signals and muscle contraction). By forming up to 8 to 12 coordination bonds with oxygen atoms in amino acid side chains, calcium stabilizes the tertiary structure of numerous catalytic and structural proteins. Cytosolic calcium ion levels are normally maintained at very low concentrations [3–4 orders of magnitude below extracellular fluid (ECF) levels]. The second messenger response occurs when calcium ions flood into critical cytosolic compartments in response to first message stimuli.

Additionally, dissolved calcium in the circulating blood and ECF of all vertebrates supports such diverse functions as blood clotting and neuromuscular signal transmission. Calcium is not consumed in the exercise of these metabolic functions.

ECF $[Ca^{2+}]$ is tightly maintained at approximately 4.4 to 5.2 mg/dL (1.1–1.3 mmol/L). The regulatory apparatus behind this constancy consists of parathyroid hormone (PTH), calcitonin, and 1,25-dihydroxyvitamin D $[1,25(OH)_2D]$, acting jointly through control of intestinal

calcium absorption efficiency, bone resorption, and the renal excretory threshold for calcium.

Secondary Functions

Effects on the Size and Strength of the Nutrient Reserve (Bone Mass)

Calcium is lost continuously from the body through shed skin, hair, nails, sweat, and excreta. For this reason, land-living vertebrates, needing a continuous supply of calcium, have evolved an internal reserve, in the form of bone. Because bone also serves structural/mechanical functions, the reserve has become far larger than would be needed solely to protect calcium's primary functions. It is for this reason that the primary functions themselves are not threatened by deficient calcium intake, or enhanced by calcium repletion.

The bony reserves are accessed by a process termed “bone remodeling.” Bony tissue is continuously renewed by first resorbing preexisting volumes of bone and then subsequently replacing them with new bone. Mineralization of the new bone occurs at a rate that is the integral of the prior several days of osteoblast activity, and for that reason tends to be relatively constant over the short term. By contrast, osteoclastic bone resorption is controllable minute by minute. Thus, by modulating bone resorption, the body can, in effect, withdraw calcium from, or cause it to be taken up by, bone whenever ECF $[Ca^{2+}]$ departs from optimal levels.

When daily absorbed calcium intake is less than that needed to offset daily calcium losses, bone resorption exceeds bone formation and the bony reserves are depleted. This occurs by net destruction of microscopic volumes of bony tissue and scavenging of the calcium released in the process. Such decrease in skeletal mass results in a corresponding reduction in strength. Additionally, bone remodeling itself directly contributes to bony structural weakness (2), insofar as the remodeling locus is, for the several months of its life cycle, depleted of its normal complement of bony material, thereby greatly weakening the involved microscopic bony elements.

The principal purpose of calcium intake during growth is to support the accumulation of the skeletal mass called for in the genetic program, that is, the building of a large calcium reserve. During the adult years, intake serves to (i) offset daily losses, thus preventing unbalanced withdrawals from the skeletal reserves, with their inevitable, associated reduction in bony strength; and (ii) reduce the level of bone remodeling to the minimum

needed for optimum structural maintenance (2). These two effects are the basis for the protective effect of calcium with respect to osteoporosis.

Intraluminal Effects of Unabsorbed Dietary Calcium

Net absorption efficiency for ingested calcium is of the order of 10% to 15% (see later). Accordingly, up to 90% of dietary and supplemental calcium remains in the intestinal lumen and is excreted as a component of the feces. At high calcium intakes, unabsorbed calcium amounts to 1000 mg (25 mmol) per day or more. This unabsorbed calcium complexes with other constituents of the digestive residue, blocking their absorption or neutralizing their luminal actions (3). This occurs, for example, with oxalic acid, which may be either present in ingested plant foods or produced by bacterial degradation of unabsorbed food fatty acids. The formation of calcium oxalate in the gut lumen reduces oxalate absorption and hence the renal oxalate load. It thereby reduces the risk of kidney stones. Similarly, the calcium ion complexes directly with free fatty acids and bile acids in the digestate substances, which, in their free form, act as mucosal irritants. In colon cancer-prone individuals, these irritants would otherwise serve as cancer promoters. These intraluminal actions are the basis for the protective effects of high calcium intakes on risk of renal stone disease and colon cancer.

Additionally, calcium complexes with dietary phosphorus, blocking its absorption to some extent. This is the basis for the use of calcium salts as a part of the control of hyperphosphatemia in patients with end-stage renal disease (ESRD). Every 500 mg of ingested calcium (whether from foods or supplements) binds ≈ 166 mg of coingested phosphorus, preventing its absorption (4).

"Off-Loop" Effects of Alterations in Calcium Homeostasis

When calcium intake is low, PTH is secreted to improve renal calcium conservation and intestinal absorption efficiency, the latter through 1- α -hydroxylation of 25(OH)D to 1,25(OH) $_2$ D in the kidney. The calcium-conserving effects of these hormones are part of a classical negative feedback loop, in the sense that 1,25(OH) $_2$ D, by increasing calcium absorptive extraction from food, counteracts to some extent the original stimulus to PTH secretion and 1,25(OH) $_2$ D synthesis.

In addition to these functions within the feedback control loop, 1,25(OH) $_2$ D binds to membrane receptors in many tissues not directly involved in calcium regulation (3). These include vascular smooth muscle cells and adipocytes. These effects are termed "off-loop," because they occur as a result of reduced ECF $[Ca^{2+}]$ but do not act to change that level. Hence, they do not influence the signals that caused them in the first place, that is, they are not a part of the regulatory feedback loop. The cell membrane receptors are linked to calcium channels that open and let calcium ions into the cytosol, where they may trigger their usual second messenger function (but without the normal first messenger). The presence of high cytosolic calcium levels, when dietary calcium is low, has given rise to the term "calcium paradox disease." In individuals with limited control of cytosolic $[Ca^{2+}]$, this rise in cytosolic calcium triggers inappropriate, tissue-specific

cell activity, for example, smooth muscle contraction in arterioles and adipogenesis in fat cells. These relationships are the basis for the protective effects of high calcium intake against hypertension and obesity, and probably for premenstrual syndrome and polycystic ovary syndrome as well (3).

The Internal Calcium Economy

The adult human body contains approximately 1000 to 1300 g (25,000–32,500 mmol) of calcium, with more than 99% being locked up in bones and teeth. Low hydration of bone, together with the insolubility of hydroxyapatite (the principal form of calcium phosphate in mineralized tissues), means that most body calcium is effectively exterior to the ECF and accessible only by cellular action (e.g., osteoclastic bone resorption).

The ECF, which is the locus of all body calcium traffic, contains about 1 g (25 mmol) calcium (i.e., $\approx 0.1\%$ of total body calcium). Soft tissues contain another 7 to 8 g (175–200 mmol) of calcium, mostly locked up in intracellular vesicles, which store calcium for its critical, second messenger function. The calcium homeostatic regulatory apparatus functions solely to maintain the constancy of the concentration of the ≈ 1 g of calcium in the ECF. In healthy midlife adults, ECF calcium turns over at a rate of approximately 650 mg/day (≈ 10 mg/kg/day), with bone mineralization and resorption accounting for half to two-thirds of that traffic.

Figure 1 displays the principal organs involved in the transfers that comprise the traffic of the calcium economy, together with the sizes of those transfers in and out of the system. The values shown are typical of the

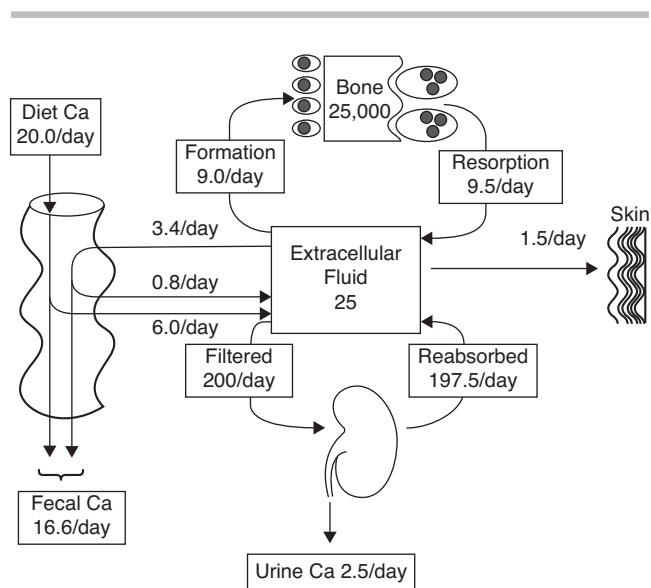

Figure 1 Principal routes of calcium entry into and exit from the extracellular fluid of an adult human. The values for bone and ECF are total masses (mmol); transfer rates are given in mmol/day and represent typical values. (To convert to milligrams, multiply values shown by 40.) Total body balance in this illustration is -0.5 mmol/day. Source: Copyright Robert P. Heaney, 1996, 2004; used with permission.

calcium economy of a middle-aged woman. In considering the magnitudes of these transfers, it is important to recognize that they do not vary independent of one another. An increase in absorption, for example, produces an immediate decrease in bone resorption. This linkage is mediated by the PTH-calcitonin-vitamin D regulatory apparatus.

Absorption

Calcium is absorbed mainly from the small intestine by a combination of active, transcellular transport and passive, paracellular diffusion. The active transport component is mediated by a vitamin D-dependent calcium-binding protein ("calbindin") that shuttles calcium ions from the luminal brush border to basolateral portions of the cell membrane, where calcium is released into the ECF. Calbindin activity is highest in the duodenum and drops along the length of the remaining bowel (including the colon). Accordingly active transport capacity is greatest in the duodenum. However, the residence time of the digestate in the duodenum is short, and most of the actual mass transport occurs in the jejunum and ileum, where residence time is longer.

The partition of absorption between the active and the passive mechanisms is not well studied, but data from various sources suggest that, at nutritionally relevant intake loads (i.e., 7.5+ mmol/meal), passive absorption amounts to approximately 15% of intake. Fractional absorption above that value thus reflects the vitamin D-mediated active transport component. The latter is highly variable, both because it is physiologically regulated in response to body need for calcium, and, in part, because it is often limited by vitamin D availability. The interactions between intake load of calcium and its active absorption are complex and are summarized in Figure 2. As measured fractional absorption is typically on the order of

0.30 to 0.32; it follows that the active transport component amounts to approximately 0.16 (16%). As is shown in Figure 2, the 16% isogram intersects the dashed line for 5 mmol (200 mg) net absorption at an intake of approximately 1200 mg (30 mmol), and thus designates the oral intake needed to maintain total body equilibrium. When vitamin D status is less than optimal, the body is generally unable to maintain active absorption at a 16% level and absorption occurs along lower and lower isograms until, at severe vitamin D deficiency, active absorption is zero. As is shown in Figure 2, intake at such absorption values would need to be in the range of 3000 mg/day to ensure absorption of sufficient calcium to offset obligatory losses.

Figure 3 shows the calcemic rise above baseline in healthy adults for a 500-mg calcium supplement source ingested as part of a low-calcium breakfast. It illustrates a number of features of calcium absorption: (i) a delay of approximately 30 minutes before serum calcium begins to rise, reflecting gastric residence time; (ii) peak calcemia at 3 to 5 hours after ingestion, indicating continuing absorptive input throughout that period of time; (iii) a degree of calcemia approximating a 1% rise for every 100 mg calcium ingested, that is, a perturbation that is within the usual normal range for serum calcium and hence effectively undetectable outside of a research context; and (iv) gradual return to baseline by 9 to 10 hours. Tracer studies show that calcium absorption is effectively completed by five hours after ingestion (5), and the slow fall to baseline after the peak reflects offsetting declines in other inputs into the ECF.

It is commonly considered that calcium salts must be dissociated to be absorbed, and hence that solubility predicts absorbability. However, this is probably incorrect. The pH of the digestate in the small intestine is close to neutral, and it is likely that most of the digestate calcium is complexed with prevailing anions in the digestate.

Figure 2 Relationship of vitamin D-mediated, active calcium absorption, calcium intake, and net calcium gain across the gut. Each of the contours represents a different level of active absorption above a baseline passive absorption of 12.5%. (The values along each contour represent the sum total of passive and variable active absorption.) The horizontal dashed lines indicate 0 and 5 mmol/day net absorption, respectively. The former is the value at which the gut switches from a net excretory to a net absorptive mode, and the latter is the value needed to offset typical urinary and cutaneous losses in mature adults. Source: Copyright Robert P. Heaney, 1999. Reproduced with permission.

Figure 3 Time course of the rise in serum calcium following a single oral dose of a commercial calcium carbonate preparation (containing 500 mg calcium) taken as part of a light, low-calcium breakfast. Error bars are 1 SEM. Source: Copyright Robert P. Heaney, 2001, 2004; used with permission.

Aqueous solubility of calcium salts spanning 4 to 5 orders of magnitude has been shown to have little or no effect on absorbability if the calcium source is coingested with food (6). Double-tracer studies have demonstrated absorption of insoluble calcium complexes *without prior dissociation* (7). Thorough dispersion of calcium salts among food particulates is probably more important than actual solubilization. Additionally, continuous slow release of calcium from the stomach, exposing the duodenal mucosa to only small amounts of calcium at a time, substantially improves absorption (Figure 4) (8).

Figure 4 Time course of serum calcium tracer concentration following oral dosing of 1000 mg tracer-labeled calcium, either as a single bolus dose ("single") or as 17 divided doses of 59 mg each ("multiple") given over an 8-hour period. "Specific activity" is a measure of tracer concentration in the calcium contained in a serum sample. Source: Copyright Robert P. Heaney, 2002; used with permission.

Excretion

Calcium leaves the body through unabsorbed digestive secretions, through sweat and shed skin, hair, and nails, and through urine (Fig. 1). In nonexercising adult humans with typical calcium intakes, digestive calcium losses amount to approximately 120 mg/day, cutaneous losses amount to approximately 60 mg/day, and urinary losses amount to approximately 120 mg/day, with great individual variability around these figures. Only the urinary loss is physiologically regulated by the system controlling calcium homeostasis, and much of even the urinary calcium represents obligatory loss, that is, excretion determined by forces outside of the calcium regulatory system (9), such as salt intake and net endogenous acid production (as, for example, from metabolism of S-containing amino acids). On average, urine calcium rises by approximately 45 mg (1.1 mmol) for every 1000 mg (25 mmol) increase in calcium intake. This increase is a reflection of the small absorptive calcemia (Fig. 3), which produces a corresponding rise in the filtered load of calcium.

In adults, the primary purpose served by ingested calcium is the offsetting of obligatory excretory losses, thus protecting the skeletal reserves and thereby preserving their structural integrity. Ingested calcium, thus, does not so much "go" to bone as prevents net removal of calcium from bone.

INDICATIONS AND USAGE

Calcium is a nutrient and would normally be ingested as a component of food. However, except for dairy foods, modern diets, especially seed-based plant foods (which are the basis of most contemporary diets), are calcium-poor diets. Hence, for many individuals, achieving an adequate calcium intake may be difficult without recourse to supplements or calcium-fortified foods. (The latter are effectively equivalent to taking a supplement along with the otherwise unfortified food.)

Supplementation to Achieve Recommended Intake Levels

Diets free of dairy foods typically contain no more than 200 to 300 mg calcium, far below currently recommended intakes (Table 1). Supplementation (or fortification) will often be required to meet optimal intake objectives.

Table 1 Estimated Average Requirements (EARs) for Calcium and the Corresponding RDAs (mg/day)

Age range	EAR	RDA ^a
Infants, 7–12 mo	270	350
Children		
1–3 yr	500	600
4–8 yr	800	1000
Boys and girls, 9–18 yr	1300	1550
Men and women		
19–50 yr	1000	1200
>50 yr	1200	1450

^aUsing an estimated 10% coefficient of variation of individual requirements around the population mean.

Source: From Ref. 10.

Since absorption efficiency is inversely proportional to the logarithm of the ingested load (11), absorption is maximized by a divided dose regimen (e.g., 3× per day; Fig. 4). Also, because delivery of calcium to the absorptive sites in the upper small intestine is optimized under meal conditions, it is best to take calcium supplements with meals. (*N.B.*: Fortified foods tend, automatically, to meet both objectives.)

Preparations

The nutritional preparations of calcium include mainly salts with such anions as carbonate, citrate, phosphate, lactate, acetate, fumarate, and citrate-malate (CCM). In addition, salts with gluconic acid may occasionally be found, and calcium chelates with amino acids are also marketed. The calcium content (i.e., “elemental” calcium) varies from 40% for the carbonate salt to ≈13% for CCM. For phosphate binding in ESRD, the acetate salt is more commonly used. In the United States, most preparations come in the form of swallowable or chewable tablets, with calcium contents ranging from 200 to 600 mg per tablet.

Bioavailability is approximately the same for all the leading salts, although CCM and the chelates tend toward the high end of the range and the gluconic acid salts toward the low end. Absorbability of the salt is only very weakly related to solubility, and gastric acid is not necessary for calcium absorption if the supplement is taken (as recommended) with meals. The most extensive, side-by-side comparisons have involved the carbonate and citrate salts, and the bulk of the evidence for such comparisons indicates approximately equal absorbability for the two sources, with perhaps a slight edge for the carbonate salt (12). Poor pharmaceutical formulation will impede disintegration and hence impair absorption, a problem encountered with many generic calcium supplement products sold in the 1980s and early 1990s (13). For this reason, preference should be given to supplements that meet United States Pharmacopeia (USP) disintegration standards, and, even better, to those that have demonstrated bioavailability.

A growing variety of fortified foods has been available since 1999. As noted, fortification tends to improve the nutritional value of low-calcium foods and, to some extent, it can be thought of as equivalent to taking supplements with meals. However, interactions between added calcium and various food constituents during food processing and storage may alter the absorbability characteristics of the former. For example, it was noted during the early days of juice supplementation that CCM was well absorbed from orange and grapefruit juices, and even better from apple juice, but poorly from lemon juice. These differences could not have been predicted from what was known of food chemistry. Hence, with fortified foods as with supplements, actual bioavailability of the product reaching the consumer should be demonstrated.

When calcium is added to beverages (such as orange juice or soy beverage), an additional problem arises. Solubility of the principal calcium salts is relatively low, and serving size portions of such beverages would not sustain in solution more than a small fraction of the calcium content of, say, a comparable serving of milk. Hence, such fortification almost always requires physical suspension of a particulate. In some beverages, this suspension is so

poor that the calcium settles as a dense sludge at the bottom of the beverage container and may, accordingly, not be ingested at all (14).

Supportive Therapy as a Part of Antiosteoporosis Pharmacotherapy

Current antiosteoporosis pharmacotherapy includes bisphosphonates, selective estrogen receptor modulators (SERMs), estrogen, and anabolic agents such as the fluoride salts, PTH derivatives such as teriparatide, and RANK-ligand antibodies and cathepsin-K inhibitors. All have at least stabilization of bone mass as their goals. Some of them, such as the bisphosphonates, can lead to slow, steady-state bone gain (0.5–1.0% per year), and the anabolic agents can produce as much as 8% to 10% bone gain per year. To support this increase, especially for the anabolic agents, calcium intake from diet must usually be augmented by supplements. Optimal doses for calcium during pharmacotherapy have not been established. However, all the bisphosphonates and SERMs have been tested only with 500 to 1000 mg supplemental calcium, whereas fluoride has been shown to produce bone hunger calling for as much as 2500 mg of calcium per day. Only estrogen has been studied with and without supplemental calcium, and here the evidence is very clear: bony effects of estrogen are augmented two- to threefold, and estrogen dose can be reduced by half if calcium intake is above 1000 mg/day (15,16). With the more potent anabolic agents, a calcium phosphate preparation may be preferable, so as to ensure an adequate intake of both of the components of bone mineral and to compensate for the intestinal binding of diet phosphorus by high-dose calcium supplementation. The high phosphorus loads of the phosphate salts produce no adverse metabolic consequences, and calcium phosphate supports bone anabolism fully as well as the carbonate salts.

Ancillary Therapy for Prevention or Treatment of Miscellaneous Disorders

Hypertension, pre-eclampsia, colon cancer, renolithiasis, premenstrual syndrome, polycystic ovary syndrome, and obesity—all multifactorial disorders—have each been shown to have a calcium-related component (3), and for several of them, calcium supplementation has been shown in randomized-controlled trials to reduce incidence and/or severity. Optimal calcium intake for this protection has not been established for any of the disorders concerned, but several threads of evidence indicate that total intakes of 1200 to 1800 mg of calcium per day may be sufficient. The role of calcium in these disorders has been described earlier (see sections “intraluminal effects of unabsorbed dietary calcium” and “off-loop effects of alterations in calcium homeostasis”). Specific pharmacotherapy of any of the disorders concerned should always be accompanied by an adequate calcium intake, using supplements if necessary.

CONTRAINDICATIONS

There are few, if any, true contraindications to calcium supplementation. In general, supplementation moves

contemporary intakes into the range that would have been the Paleolithic standard, and hence helps to normalize modern diets. However, patients receiving calcitriol therapy or suffering from disorders such as sarcoidosis, in which calcium absorption may be high, should not take supplements except under medical supervision.

PRECAUTIONS AND ADVERSE REACTIONS

Calcium supplements may bind with tetracycline antibiotics and hence reduce their absorbability. The element has also been reported to interfere slightly with thyroxine absorption. Hence, a person requiring both calcium and thyroid replacements should take them at different times of the day or have plasma thyroxine and thyroid-stimulating hormone (TSH) levels checked to ensure that the thyroid dose produces the desired therapeutic effect. Both calcium salts and high-calcium foods reduce absorption of non-heme iron ingested at the same meal in unprepared subjects. However, chronic supplementation studies show no long-term deterioration in iron status in adults and no interference with augmenting iron status during growth (17). The single-meal tests that are used to demonstrate this interference could not have detected physiological upregulation of iron absorption.

Adverse reactions tend to be extremely rare and mostly idiosyncratic. Although constipation is often said to be a consequence of taking calcium carbonate, the evidence is scant (18), and in several randomized-controlled trials, the difference in degree of constipation between the calcium- and placebo-treated groups has generally been small and usually not statistically significant.

OVERDOSAGE

The Food and Nutrition Board of the Institute of Medicine, in its 1997 recommendations, set a tolerable upper intake level for calcium to be 2500 mg/day (9). However, it is important to note that there has never been a reported case of overdosage of calcium from food sources, even at continuing intakes over 6000 mg/day. Supplement intakes above 2500 mg/day are occasionally associated with a syndrome similar to the milk alkali syndrome. The pathogenesis of the hypercalcemia seen in this condition is complex, but there is usually hypoperfusion of both the kidneys and the skeleton, the two most important internal regulatory organs for calcium. The condition can usually be managed by giving attention to adequate hydration and maintenance of blood flow to these critical organs. Except as support for the most potent osteoporosis pharmacotherapy, or in management of the hyperphosphatemia of ESRD, there is no known reason to use supplements at a dose above 2500 mg of calcium per day.

REGULATORY STATUS

Calcium supplements are regulated as foods in the United States. Bioavailability is not a regulated characteristic of

marketed supplement products. Nevertheless, because of pharmaceutical formulation and food matrix effects on absorbability, bioavailability of different preparations of the same salt (e.g., calcium carbonate) may vary over a twofold range.

L-Carnitine, Acetyl-L-Carnitine, and Propionyl-L-Carnitine

Charles J. Rebouche

INTRODUCTION

L-Carnitine [known chemically as *R*(-)- β -hydroxy- γ -(*N,N,N*-trimethylammonio)butyrate; molecular weight: 161.2 g/mol] is a water-soluble quaternary amine that facilitates lipid metabolism. Only the L isomer is biologically active. Humans acquire varying amounts of L-carnitine from dietary sources, but a dietary requirement has not been established. The goal of this chapter is to survey the literature on the clinical findings on L-carnitine and its esters acetyl-L-carnitine and propionyl-L-carnitine. Due to space constraints, this is not an exhaustive review. Readers are directed to the references for more information.

BIOCHEMISTRY AND FUNCTIONS

The human body synthesizes L-carnitine from the essential amino acids lysine and methionine in amounts that are limited but adequate for the maintenance of normal health (1). L-Carnitine participates in reversible transesterification reactions, in which an acyl group is transferred from coenzyme A to the hydroxyl group of L-carnitine (Fig. 1). Acetyl-L-carnitine, propionyl-L-carnitine, and other esters are biosynthesized in this manner. Carnitine and acetyl-L-carnitine (and lesser amounts of other esters of carnitine) are also obtained from the diet (1).

Transfer of Long-Chain Fatty Acids from Cytoplasm into Mitochondria

Long-chain fatty acids, as free acids or coenzyme A esters, cannot cross the mitochondrial inner membrane. In contrast, long-chain acylcarnitine esters rapidly cross this membrane, facilitated by a carrier protein, carnitine-acylcarnitine translocase (CACT) (2). In the cytoplasm, transesterification of long-chain fatty acids from coenzyme A to L-carnitine is catalyzed by carnitine palmitoyltransferase I (CPT I), an integral protein of the mitochondrial outer membrane. This enzyme serves as the primary regulator in partitioning fatty acids toward oxidation in mitochondria or triglyceride synthesis, and its activity is regulated principally through inhibition by malonyl-CoA (3). On the matrix side of the mitochondrial inner membrane, the acyl group of the carnitine ester is transferred to intramitochondrial coenzyme A and carnitine is released (2). This reaction is catalyzed by carnitine palmitoyltransferase II (CPT II), an enzyme bound to the surface of the membrane (2). L-Carnitine, either nonesterified or as a short-chain acyl ester, may then exit the mitochondrion via CACT (Fig. 2).

Figure 1 Transesterification reaction between L-carnitine and coenzyme A.

Transfer of Chain-Shortened Fatty Acids from Peroxisomes to Mitochondria

Very long-chain fatty acids are not metabolized in the mitochondria. Instead, they enter peroxisomes and undergo one or more β -oxidation cycles, leading to the generation of medium-chain acyl-CoA. These acyl groups are then transesterified by carnitine octanoyltransferase for export from the mitochondria (2). Medium-chain acylcarnitine esters exported from peroxisomes are transported into mitochondria by CACT, and the acyl moieties are transesterified to coenzyme A and oxidized (Fig. 2) (2).

Modulation of the Acyl-CoA/CoA Ratio in Cellular Compartments

Coenzyme A participates in many metabolic processes in the cellular cytoplasm and organelles. However, neither coenzyme A nor its thioesters can cross the membranes separating these compartments. Thus, in each compartment, sufficient nonesterified coenzyme A must be made available to maintain metabolic activities in that part of the cell. Because of its ability to be transported across organelle membranes and undergo rapid transesterification with coenzyme A, L-carnitine facilitates availability of adequate amounts of the deacylated coenzyme. In mitochondria, the amount of acetyl-CoA generated from rapid β -oxidation of fatty acids or carbohydrate utilization

Figure 2 L-Carnitine and acetyl-L-carnitine transport and function. *Abbreviations:* Carn, L-carnitine; AcCarn, acetyl-L-carnitine; OCTN2, organic cation transporter 2; UnTr, unidentified transporter(s); LCA-CoA, long-chain acyl-coenzyme A; MCA-CoA, medium-chain acyl-coenzyme A; VLCA-CoA, very long-chain acyl-coenzyme A; LCA-Carn, long-chain acylcarnitine esters; MCA-Carn, medium-chain acylcarnitine esters; Ac-CoA, acetyl-coenzyme A; CPT I, carnitine palmitoyltransferase I; CPT II, carnitine palmitoyltransferase II; CAT, carnitine acetyltransferase; COT, carnitine octanoyltransferase; CACT, carnitine-acylcarnitine translocase; PDH, pyruvate dehydrogenase complex.

may exceed the capacity of the citric acid cycle to release the coenzyme. Transesterification of acetyl units to L-carnitine, catalyzed by carnitine acetyltransferase (CAT), frees intramitochondrial coenzyme A for participation in subsequent cycles of substrate utilization (3,4). Lowering of the acetyl-CoA/CoA ratio stimulates pyruvate oxidation, secondary to an increase in pyruvate dehydrogenase complex activity (4). Acetyl-L-carnitine can be removed from the mitochondrion via CACT for use in the cytoplasm, for export and use in other cells or tissues, or for excretion (3,4). This function has long been viewed primarily as a means to dispose of acetyl units from mitochondria. However, export of acetyl-L-carnitine from some cells and tissues (e.g., liver and kidney) may be important for supply of this metabolite to other tissues (e.g., brain), where it may have specific functions in addition to its use as a substrate for energy production. Moreover, by modulating the intramitochondrial acetyl-CoA/CoA ratio, L-carnitine plays a significant role in regulating glucose metabolism in skeletal muscle and heart (4).

Membrane Phospholipid Remodeling

L-Carnitine and extramitochondrial CPT are important modulators of long-chain fatty acid utilization for membrane phospholipid biosynthesis and remodeling. L-Carnitine acts as a reservoir of long-chain fatty acids for incorporation into erythrocyte membrane phospholipids during repair after oxidative insult (2) and for use in the synthesis of dipalmitoylphosphatidylcholine, the major component of surfactant, in lung alveolar cells (2).

Other Reported Actions of L-Carnitine and/or Its Acetyl and Propionyl Esters

L-Carnitine may mimic some of the actions of glucocorticoids *in vivo*. In HeLa cells, L-carnitine reduces glucocorticoid receptor- α affinity for its steroid ligand and triggers nuclear translocation of the receptor (5). It suppresses glucocorticoid receptor-mediated tumor necrosis factor- α and interleukin-12 release by human primary

monocytes stimulated with lipopolysaccharide *ex vivo* (5). All of these effects of L-carnitine are concentration dependent. In rats and mice, L-carnitine is found to markedly suppress liposaccharide-induced cytokine production, improving their survival during cachexia and septic shock (5). In humans, L-carnitine supplementation of surgical and AIDS patients decreased serum tumor necrosis factor- α concentration (5). Glucocorticoids also increase the expression and activity of urea cycle enzymes. Hyperammonemia associated with chronic valproic acid therapy and with several inborn errors of metabolism, including CACT deficiency and medium-chain acyl-CoA dehydrogenase deficiency, is attenuated by L-carnitine administration. It has been experimentally found that L-carnitine supplementation protects against lethal ammonia intoxication in mice (6). One suggested mechanism for these effects of L-carnitine is increased synthesis and activity of urea cycle enzymes, a process also responsive to glucocorticoids.

L-Carnitine is a peripheral antagonist of thyroid hormone action in some tissues (7). It inhibits thyroid hormone entry into cell nuclei. In a controlled clinical trial, L-carnitine was shown to reverse or prevent some symptoms of hyperthyroidism (7).

Acetyl-L-carnitine may directly or indirectly reverse age-associated mitochondrial decay (8). It acts as a chaperone to protect macromolecules, including CAT, from structural alteration and/or loss of function. Acetyl-L-carnitine partially reverses age-associated loss of mitochondrial membrane potential and decline in membrane cardiolipin concentration, and protects against oxidative damage to mitochondrial DNA (8).

L-Carnitine inhibits arachidonic acid incorporation into platelet phospholipids, agonist-induced arachidonic acid release, and arachidonic acid-induced NADPH (nicotinamide adenine dinucleotide phosphate)-oxidase activation (9). It has been proposed and some evidence has been obtained to support this notion that acetyl-L-carnitine stimulates or upregulates expression of heat shock proteins, redox-sensitive transcription factors, and sirtuins that protect against oxidative cellular damage (10). These actions may be particularly important in modulating the aging process and in slowing the progression of neurodegenerative diseases.

PHYSIOLOGY

Dietary Intake and Biosynthesis

Meat, fish, chicken, and dairy products are rich sources of dietary L-carnitine (1). Plant-derived foods contain very small amounts of the substance. Most commercially available infant formulas contain L-carnitine, either provided from the milk component or supplemented, as in the case of soy-protein-based formulas. There is no recommended dietary allowance or dietary reference intake for L-carnitine.

In mammals, L-carnitine is synthesized from ϵ -N-trimethyllysine, which is derived from post-translationally methylated lysine residues in proteins, and protein turnover (1). In normal humans, the rate of synthesis is estimated to be approximately 1.2 $\mu\text{mol/kg}$ body weight/day (1). The rate of L-carnitine biosynthesis is regulated by the availability of ϵ -N-trimethyllysine. Thus,

conditions that increase protein methylation and/or protein turnover may increase the rate of L-carnitine biosynthesis (1).

Bioavailability

Dietary L-carnitine may be absorbed through active or passive mechanisms. Evidence from several *in vivo* and *in vitro* studies indicates that L-carnitine is actively transported from the small intestinal lumen into enterocytes (11). However, the preponderance of data suggests that intracellular L-carnitine in the intestinal mucosa does not cross serosal membranes by an active transport mechanism. Absorption of dietary L-carnitine and L-carnitine supplements appears to occur primarily by passive diffusion (11). In humans, approximately 54% to 87% of dietary L-carnitine is absorbed, depending on the amount in the diet. The bioavailability of dietary supplements (0.6–4 g/day) is 15% to 20% (11,12). Unabsorbed L-carnitine is degraded by microorganisms in the large intestine. Major metabolites identified are trimethylamine oxide in urine and γ -butyrobetaine in feces (11,12). Bioavailability of oral acetyl-L-carnitine has not been studied in normal healthy humans.

Distribution in Tissues, Fluids, and Cells

L-Carnitine and acylcarnitine esters are present in all tissues. In most tissues and cells, they are present in higher concentration than in the circulation. For example, in human skeletal muscle and liver, respectively, nonesterified L-carnitine is concentrated 76-fold and 50-fold from that in serum (estimated from data in Ref. 13).

Tissue Accumulation

L-Carnitine and acetyl-L-carnitine are concentrated in most tissues via high-affinity, Na^+ -dependent organic cation transporter OCTN2 (14). K_t for L-carnitine binding is 3 to 5 μM ; OCTN2 binds acetyl-L-carnitine and propionyl-L-carnitine with comparable affinity. This protein is highly expressed in heart, placenta, skeletal muscle, kidney, pancreas, testis, and epididymis and weakly expressed in brain, lung, and liver. L-Carnitine entry into the liver occurs via a low-affinity ($K_t = 5 \text{ mM}$) transporter, probably distinct from OCTN2. Several other L-carnitine transporters have been identified, including OCTN1, OCTN3, and ATB⁰⁺, and Oat9S (2,15). Specific roles for these transporters in carnitine metabolism in humans have not been determined.

Homeostasis, Renal Reabsorption, and Excretion

Circulating L-carnitine concentrations are maintained at a fairly constant level of around 50 μM , predominantly through efficient reabsorption by the kidney (11). At a filtered load of 50 $\mu\text{mol/L}$, the efficiency of L-carnitine and acylcarnitine ester reabsorption is 90% to 98%. However, as the filtered load of L-carnitine increases, for example, after consumption of a dietary supplement or after intravenous infusion, the efficiency of reabsorption declines rapidly. Physiologically, the efficiency of L-carnitine reabsorption is sensitive to the amount in the diet as well as the differences in the macronutrient content of the diet. Clearance of acylcarnitine esters is often higher than that of nonesterified L-carnitine. Experimental

studies have shown that in rats and humans, kidneys are able to synthesize acetyl-L-carnitine from L-carnitine and either acetoacetate or β -hydroxybutyrate, and that L-carnitine, acetyl-L-carnitine, and γ -butyrobetaine (also synthesized in human kidneys) are secreted from mucosal cells into the tubular lumen (11). Because the kinetics of transport of these metabolites by the sodium-dependent L-carnitine transporter are not different, the relative proportions appearing in urine reflect not only those in the glomerular filtrate but also those in the renal tubular epithelium that are secreted into the lumen. Thus, under conditions of rapid intracellular synthesis of acylcarnitine esters or direct accumulation from the circulation, secretion of these species will lead to a higher proportion of acylcarnitine esters in urine compared to that in the circulation. By inference, kidneys may be substantially involved in the regulation of circulating acylcarnitine ester concentrations (11).

L-CARNITINE DEFICIENCIES

L-Carnitine deficiency is defined biochemically as abnormally low concentration ($<20 \mu\text{M}$) of nonesterified L-carnitine in plasma (2). A concentration ratio of acylcarnitine esters/nonesterified L-carnitine of 0.4 or greater in plasma is also considered abnormal. Nutritional L-carnitine deficiency has not been shown to occur in the absence of other mitigating factors (2).

Primary L-carnitine deficiency occurs as a result of defects in the gene coding for the plasma membrane L-carnitine transporter OCTN2 (16). Characteristic features of this disease are cardiomyopathy, hypoketotic hypoglycemia, and muscle weakness. Secondary carnitine deficiency occurs in association with genetic diseases of organic acid metabolism and in genetic diseases involving defects in fatty acid oxidation. Secondary carnitine deficiency has been described in patients with end-stage renal disease requiring maintenance hemodialysis. Secondary carnitine deficiency has been observed during chronic use of drugs, including valproic acid, cisplatin, ifosfamide, zidovudine, and pivalic acid-containing prodrugs (17–20).

INDICATIONS AND USAGE

L-Carnitine, acetyl-L-carnitine, and/or propionyl-L-carnitine may be used for replacement therapy to restore normal carnitine concentrations and/or abnormal nonesterified-to-esterified carnitine ratio. They may be used as supplements to increase the carnitine load of the body and/or increase the flux of carnitine among compartments. In some conditions, both replacement therapy and supplementation are appropriate. For primary and some secondary carnitine deficiencies (see earlier), L-carnitine is used for replacement therapy.

L-Carnitine Supplementation in Neonatal Nutrition

L-Carnitine has been described as a conditionally essential nutrient for infants. For the last 25 years, commercial enteral infant formula products have included L-carnitine, where necessary, to achieve an L-carnitine concentration similar to that in human milk ($\sim 60 \mu\text{mol/L}$). Bovine milk-

based formulas typically contain a higher concentration of L-carnitine than does human milk. On the other hand, premature infant formulas, both enteral and parenteral, typically do not include L-carnitine at the time of manufacture, but are sometimes supplemented at the time of use. The rationale for supplementation is twofold: Infants utilize lipids as a primary source for energy and growth after birth, requiring a high rate of mitochondrial oxidation, and the concentration of L-carnitine in infant circulation and tissues typically is lower without supplementation than in infants fed human milk or formulas containing carnitine. Studies in premature infants typically have focused on the effect of L-carnitine supplements on growth rate and morbidity, with mixed results. In one double-blind, placebo-controlled, randomized trial of L-carnitine supplementation in premature infants 28 to 34 gestational weeks of age at birth, no differences in two-week weight gain over 8 weeks were observed between supplemented and nonsupplemented infants (21). More recently, in another prospective, randomized, placebo-controlled, double-blinded study, 29 premature neonates received carnitine supplementation (20 mg/kg body weight/day) or placebo for up to eight weeks. Supplemented neonates regained their birth weight more rapidly than placebo group neonates, indicating that L-carnitine supplementation may promote more rapid catch-up growth (22). An extensive review of these and many more relevant studies has been published (23). For infants expected to be on parenteral nutrition for seven days or longer, supplementation with L-carnitine 10 to 20 mg/kg body weight/day, given intravenously or orally, is recommended (23).

L-Carnitine Replacement Therapy and Supplementation in End-Stage Renal Disease

Regular L-carnitine supplementation in hemodialysis patients can improve lipid metabolism, antioxidant status, and anemia requiring erythropoietin and may reduce incidence of intradialytic muscle cramps, hypotension, asthenia, muscle weakness, and cardiomyopathy (24,25). The recommended dosage is 50 mg/kg body weight/day, to a maximum of 3 g/day.

L-Carnitine and Propionyl-L-Carnitine Supplementation for Cardiac Ischemia, Congestive Heart Failure, Cardiomyopathy, and Peripheral Arterial Disease

Experimental studies have shown L-carnitine to be an effective antianginal agent that reduces ST-segment depression and left ventricular end-diastolic pressure during stress in patients with coronary artery disease (25). Cardioprotective effects of L-carnitine have been observed following aortocoronary bypass grafting and following acute myocardial infarction. Carnitine administration initiated early after acute myocardial infarction attenuated left ventricular dilation and resulted in smaller left ventricular volumes (25).

L-Carnitine deficiency syndromes sometimes present with dilated cardiomyopathy and are often effectively treated with L-carnitine (26). Thus, it was suggested that cardiomyopathy progressing to congestive heart failure but not associated with inherited L-carnitine deficiency might respond to L-carnitine supplementation. A large-scale clinical trial of L-carnitine supplementation

versus placebo in 574 patients with heart failure produced promising results with regard to improvement in maximum duration of exercise, but other endpoints, including death and hospital admissions during the follow-up period, were not different between treatment groups (26). Utility of L-carnitine supplements for congestive heart failure not associated with inherited L-carnitine deficiency remains debatable (26,27).

Peripheral arterial disease is a common manifestation of atherosclerosis and is associated with reduced arterial circulation in the lower extremities. In five large, randomized, double-blind, placebo-controlled studies, with long duration of therapy, and three short-duration studies, propionyl-L-carnitine supplementation (1–3 g/day, orally) for up to one year improved initial claudication distance (distance walked before muscular symptoms appeared) and absolute claudication distance (distance at which patient stopped walking due to muscular cramps) (28). Quality of life outcomes were also improved with propionyl-L-carnitine treatment relative to placebo. Experimental and clinical studies suggest that the improvements observed in clinical trials are due to protection by propionyl-L-carnitine from the effects of oxidative stress and inflammation in ischemic tissue endothelium (28), as well as due to increased blood flow resulting from endothelium-dependent vasodilation elicited by propionyl-L-carnitine (29).

L-Carnitine Supplementation for Exercise Performance and Weight Reduction

L-Carnitine supplementation has been suggested to improve exercise performance in healthy humans. Proposed mechanisms include enhanced muscle fatty acid oxidation, altered glucose homeostasis, enhanced acylcarnitine production, modification of training responses, and altered muscle fatigue resistance (30). A review of published studies has led to the conclusion that L-carnitine supplements do not improve exercise performance in healthy humans (30–33). On the other hand, in conditions where the nonesterified L-carnitine concentration of skeletal muscle may be significantly reduced, such as in peripheral arterial disease and end-stage renal disease, L-carnitine supplementation has afforded some benefit to muscle function and exercise performance (33).

In a double-blind, placebo-controlled, crossover design clinical trial, oral administration of 4.5 g of propionyl-L-carnitine (as glycine propionyl-L-carnitine) to trained athletes significantly enhanced peak power production in resistance-trained males with significantly lower lactate accumulation (34). The incremental differences in power production were modest and were observed only after repeated short-duration Wingate cycle sprints. However, it is noted that, particularly for elite athletes, modest enhancement in performance can be highly significant in outcomes in competitive sports. Propionyl-L-carnitine may be more effective in enhancement of exercise performance than L-carnitine, because of its ability to increase nitric oxide production and vasodilation. Moreover, propionyl-L-carnitine may enhance citric acid cycle activity by providing propionyl units that can be converted to succinate.

Because of its role in facilitating fatty acid oxidation, L-carnitine has been suggested to aid in weight loss regimes. Two facts argue against this. First, there is no evidence that it facilitates, directly or indirectly, mobilization of fatty acids from adipose tissue. Second, in normal humans, the intracellular concentration of L-carnitine is not rate-limiting for transesterification of fatty acids by CPT I. Adding an increment of L-carnitine will not increase the rate at which this reaction occurs. There is no scientific evidence that L-carnitine supplements facilitate weight loss in humans.

L-Carnitine and Acetyl-L-Carnitine Replacement Therapy and Supplementation for Chronic Fatigue

L-Carnitine may improve symptoms of fatigue in humans. Use of the cancer chemotherapeutic agents cisplatin and ifosfamide is associated with fatigue. In a prospective, open-label study, improvement of symptoms of fatigue was observed in 50 nonanemic patients following L-carnitine supplementation to the chemotherapeutic regimen of cisplatin or ifosfamide (35). However, in a subsequent randomized, double-blind, placebo-controlled trial, no improvement in measures of fatigue was observed as a result of L-carnitine supplementation (36). The study included an open-label phase, in which fatigue symptoms did show some improvement with L-carnitine supplementation.

Chronic fatigue syndrome (CFS) in humans was found to be associated with low circulating acetyl-L-carnitine concentration and decreased accumulation in several brain regions (37). It has been suggested that acetyl-L-carnitine helps maintain neuronal metabolic activity by promoting glucose and lactate uptake and utilization through its role as a precursor of glutamate in neurons (38). In a randomized, open-label study of 30 patients with CFS, acetyl-L-carnitine and propionyl-L-carnitine showed beneficial effects on fatigue and attention concentration (39).

Acetyl-L-Carnitine Supplementation for Depression and Cognitive Function in the Elderly

Acetyl-L-carnitine appears to have specific and perhaps unique roles in brain metabolism. Animal studies and in vitro experiments suggest that this agent has promise in slowing or reversing memory and cognition decline as well as the decline in physical performance that normally occurs in the process of aging. In studies of the elderly, patients with depressive syndrome scored significantly lower on the Hamilton Rating Scale for Depression (modified for the elderly) following supplementation with acetyl-L-carnitine (40). Older subjects with mild mental impairment had improved scores on cognitive performance tests following such supplementation (41). A meta-analysis of the efficacy of acetyl-L-carnitine in mild cognitive impairment and mild Alzheimer disease included all identified double-blind, placebo-controlled, prospective, parallel-group studies using treatment doses of 1.5 to 3.0 g/day of acetyl-L-carnitine that were conducted between 1983 and 2000 (42). This analysis showed a significant advantage for acetyl-L-carnitine compared to placebo, with beneficial effects observed on both clinical scales and psychometric tests. The benefit of supplement use was

observed for three months, and it was found to increase over time. The typical usage recommended by vendors is 1 to 3 g/day.

L-Carnitine Supplementation in Liver Dysfunction with Hyperammonemia

Hyperammonemia occurs in some inborn errors of metabolism and as a result of drug- or toxicant-induced hepatotoxicity. Mortality and metabolic consequences of acute ammonium intoxication in mice are reduced by pharmacologic administration of L-carnitine (6). The mechanism for this effect may have two components. L-Carnitine administration normalizes the redox state of the brain (perhaps by increasing the availability of β -hydroxybutyrate and/or acetyl-L-carnitine to the brain), and it increases the rate of urea synthesis in the liver, perhaps, in part, by activation of the glucocorticoid receptor. At least part of the protective effect is associated with flux through the carnitine acyltransferases, as analogs of L-carnitine that are competitive inhibitors of carnitine acyltransferases enhance the toxicity of acute ammonium administration (6). Thus, it has been proposed that L-carnitine increases urea synthesis in the liver by facilitating fatty acid entry into mitochondria, leading to increased flux through the β -oxidation pathway, an increase of intramitochondrial reducing equivalents, and enhancement of ATP production (6). Carnitine supplementation may benefit individuals with hepatic dysfunction due to inborn errors of metabolism or chemical intoxication.

L-Carnitine and Acetyl-L-Carnitine Replacement Therapy and Supplementation in Diabetes

L-Carnitine infusion improves insulin sensitivity in insulin-resistant diabetic patients (43). Glucose oxidation is increased during L-carnitine administration, concurrent with lower plasma concentration of lactate. These observations suggest that L-carnitine activates normally depressed pyruvate dehydrogenase activity in insulin-resistant patients (43). Intravenous administration of acetyl-L-carnitine increases glucose disposal in Type 2 diabetic patients (44). Such administration appears to promote storage of glucose as glycogen, rather than increase in glucose oxidation (44).

L-Carnitine and Acetyl-L-Carnitine Replacement Therapy and Supplementation in HIV Infection

L-Carnitine and acetyl-L-carnitine ester concentrations are below normal in some human immunodeficiency virus (HIV)-infected patients undergoing antiretroviral therapy (45). L-Carnitine administration as part of antiretroviral therapy with either zidovudine or didanosine reduced lymphocyte apoptosis and oxidant stress compared to the antiretroviral regimens without L-carnitine (46).

L-Carnitine and Acetyl-L-Carnitine Supplementation in Male Reproductive Dysfunction

L-Carnitine and/or acetyl-L-carnitine supplementation may be beneficial in men with oligoasthenospermia, a condition in which low sperm count is associated with low sperm motility. Epididymal fluid contains the highest concentration of L-carnitine in the human body. L-Carnitine is secreted from the epithelium into epididymal plasma via

a testis-specific carnitine transporter (47). The very high concentration of L-carnitine in epididymal fluid provides for passive diffusion of L-carnitine into spermatozoa during transit and maturation through the epididymis. Mature spermatozoa acetylate L-carnitine to generate a pool of intracellular acetyl-L-carnitine (48). In semen obtained from 101 men with normal or abnormal spermiograms, concentrations of L-carnitine and acetyl-L-carnitine correlated positively with the number of spermatozoa, the percentage of motile spermatozoa, and the percentage of normal cells (49). A meta-analysis comparing L-carnitine and/or acetyl-L-carnitine to placebo treatment and including nine randomized, controlled clinical trials revealed significant improvements in pregnancy rate, total sperm motility, forward sperm motility, and presence of atypical sperm cells (50). The benefits of L-carnitine and acetyl-L-carnitine may be due to increased mitochondrial fatty acid oxidation, resulting in improvement in motility epididymal sperm, as well as due to the putative antiapoptotic effect(s) of carnitine in the testes (51).

ADVERSE EFFECTS

Transient diarrhea, nausea, vomiting, abdominal cramps, and/or "fish-odor syndrome" have been noted in rare cases after consumption of 2 to 6 g of L-carnitine (52).

COMPENDIAL/REGULATORY STATUS

L-Carnitine is approved as a pharmaceutical by the U.S. Food and Drug Administration for treatment of primary systemic carnitine deficiency, as well as for acute and chronic treatment of patients with inborn errors of metabolism that result in secondary carnitine deficiency (e.g., medium-chain acyl-CoA dehydrogenase deficiency, glutaric aciduria, Type 2 diabetes, methylmalonic aciduria, and propionic acidemia) (52). L-Carnitine is also approved, by the U.S. Food and Drug Administration, as a pharmaceutical for the prevention and treatment of carnitine deficiency in patients with end-stage renal disease who are undergoing dialysis (52).

CONCLUSION

L-Carnitine and esters of L-carnitine have a proven, essential role in cellular fatty acid metabolism. Beyond that, numerous other functions have been suggested by physiological and pharmacological studies in experimental animals and in humans. These include, but are not limited to, antioxidant and antiapoptotic properties, a role in membrane lipid remodeling, and modulation of gene expression. Identification of and evidence for these putative functions have led to hypotheses concerning a role for L-carnitine and its esters in promotion of physiological function (e.g., exercise performance), in prevention, slowing, or attenuation of progressive alteration or loss of physiological function (e.g., cognitive function in aging, cardiac or liver dysfunction, and male reproductive dysfunction). In some cases, establishment of a positive role for L-carnitine supplementation through blinded,

randomized clinical trials has been hampered by lack of accessibility of definitive, quantitative endpoint(s), and/or by the requirement for large sample sizes to detect small but meaningful physiological or pathological differences in a heterogeneous population. Nevertheless, it seems likely that new data will emerge from well-designed clinical trials to provide definitive answers regarding the efficacy of L-carnitine and/or its esters supplementation to promote better health and function in the human population.

β -Carotene

Elizabeth J. Johnson and Robert M. Russell

INTRODUCTION

β -Carotene (molecular formula: $C_{40}H_{56}$) is a fat-soluble plant pigment found in red, orange, and yellow vegetables and fruits. β -Carotene is converted to vitamin A (retinal, retinol, and retinoic acid), when it is in short supply in the body. It is an antioxidant—a compound that blocks the action of activated oxygen molecules that can damage cells. Dietary intake of foods containing β -carotene has been associated with cancer prevention. However, there is not enough evidence to support this. In fact, high-dose β -carotene supplementation may increase the risk of lung cancer among people already at high risk, such as smokers.

BIOCHEMISTRY AND FUNCTIONS

β -Carotene belongs to a large class of plant pigments referred to as carotenoids. It is made up of eight isoprene units that are cyclized at each end of the molecule. β -Carotene functions in plants and in photosynthetic bacteria as an accessory pigment in photosynthesis and protects against photosensitization in animals, plants, and bacteria. In humans, the only known function of β -carotene is its vitamin A activity. Other possible actions in humans include antioxidant activity, immunoenhancement, inhibition of mutagenesis and transformation, inhibition of premalignant lesions, and decreased risk of some cancers and some cardiovascular events. In the skin, β -carotene has been found to have protective effects against solar radiation damage. However, two human intervention studies that used high-dose β -carotene supplements reported an increased risk for lung cancer among smokers (1,2). In vitro and in vivo studies suggest the potential chemopreventive activity of β -carotene; that is, β -carotene itself may act as an anticarcinogen, but its oxidized products, which appear when β -carotene is present in tissue at high concentration, may facilitate carcinogenesis (3).

ABSORPTION AND METABOLISM

Because β -carotene is fat soluble, it follows the same intestinal absorption pathway as dietary fat. Release of β -carotene from the food matrix and its dissolution in the lipid phase are the important initial steps in the absorption process. β -Carotene is thought to be absorbed by the small intestinal mucosa via a passive, diffusion process. It is taken up by the mucosa of the small intestine and packaged into triacylglycerol-rich chylomicrons and is partly converted to vitamin A by a specific enzyme, β -carotene 15,15'-oxygenase (also known as carotene

mono-oxygenase or CMOI), in the intestinal mucosa. Both β -carotene and vitamin A (primarily as retinyl esters) are incorporated into chylomicrons and secreted into lymph for transport to the liver. A second cleavage enzyme (CMOII) cleaves β -carotene eccentrically at the 9'-10' position to yield β -apo-10'-carotenal and β -ionone. The significance of this reaction is uncertain, but it is clear that CMOII is a minor player with respect to the formation of vitamin A. Additional random oxidative cleavage at several double bonds in the polyene chain of β -carotene can also occur when there is not an adequate supply of antioxidants, for example, vitamin E. However, enzymatic central cleavage by CMOII plays the major role in β -carotene breakdown under normal conditions. In conditions of oxidative stress (e.g., smoking or diseases associated with oxidative stress) or when high concentrations of β -carotene are present, both central and random cleavage may occur (Fig. 1) (4).

The delivery of β -carotene to extrahepatic tissue is accomplished through the interaction of lipoprotein particles with receptors and the degradation of lipoproteins by extrahepatic enzymes such as lipoprotein lipase. β -Carotene is present in a number of human tissues, including adipose, liver, kidney, adrenal gland, and testes and is one of the major carotenoids in human diet, serum, and tissues.

In fasting serum, β -carotene is found primarily in low-density lipoproteins (LDL), but appreciable amounts are also found in high-density lipoproteins (HDL) (5-7). β -Carotene, being lipophilic, is located in the core of lipoproteins, which may explain why there is little transfer among them.

The concentration of β -carotene in human serum is highly variable and depends on a number of factors, including β -carotene intake, efficiency of absorption, and other components of the diet.

BIOAVAILABILITY

The bioavailability of a carotenoid is considered to be the fraction of ingested carotenoid utilized for normal physiological functions or storage. Information on carotenoid bioavailability is based largely on serum levels after ingestion. The bioavailability of β -carotene from food, concentrated extracts, or synthetic products is quite variable. Several human studies have reported on the serum response to β -carotene supplements. Factors that affect β -carotene bioavailability include vehicle type (supplement vs. food: processed vs. unprocessed food) and dietary factors (amount of β -carotene, fat, and fiber) (8).

Figure 1 β -Carotene conversion to vitamin A (retinal, retinol, and retinoic acid). Central cleavage by carotene monooxygenase or CMOI between bonds 15 and 15' forms retinal directly. A second cleavage enzyme (CMOII) cleaves β -carotene excentrically at the 9'-10' position. Cleavage at other bonds forms apocarotenals (CHO). Apocarotenals may be oxidized to apocarotenoic acids (-COOH), which could form retinoic acid. Apocarotenals may be oxidized to apocarotenoic acids (-COOH), which could form retinoic acid.

Compared with carrots (a source of β -carotene), supplements suspended in oil or in water from gelatin-stabilized beadlets (the form used in the major clinical trials) raise the plasma concentration approximately six-fold. This may be because a pure form of β -carotene does not need to be released from a food matrix for intestinal absorption. β -Carotene may have twice the bioavailability from fruits compared with green leafy vegetables. The percentage absorption of a single dose of β -carotene (45 mg to 39 mg) has been reported to range from 9% to 22% (9-11), but the absorption efficiency decreases as the amount of carotenoids in the diet increases (12-15). Absorption of β -carotene at dosages greater than 20 to 30 mg is very limited because of the factors such as solubility (16).

Cooking and mechanical homogenization increase the bioavailability of carotenoids from foods. The mechanism by which this occurs is most likely the disruption of the food matrix to release the carotenoid from the matrix and from protein complexes. For example, the plasma response of β -carotene has been reported to be three times greater in spinach and carrots that were pureed and thermally processed than it was when these vegetables were consumed in raw, large pieces (17). Although dietary fat facilitates the absorption of β -carotene, the amount of dietary fat does not affect the postprandial increases in plasma β -carotene concentrations, as long as there is some fat in the diet (18). However, when

β -carotene is given in the absence of fat, no detectable change in serum level occurs (19). Studies involving daily supplementation with high-dose β -carotene on plasma concentrations of other carotenoids for several years find no overall adverse effect on plasma concentrations of other carotenoids (20). The β -carotene: vitamin A (retinol) equivalency ratio of a low dose (<2 mg) of purified β -carotene in oil is approximately 2:1. The water miscible form of β -carotene is presumed to be better absorbed than the carotenoid in oil and, therefore, may have a more efficient (i.e., lower) conversion ratio. However, the efficiency of absorption of β -carotene in food is lower than that of β -carotene in oil. The Institute of Medicine of the National Academy of Sciences proposes that 12 mg of β -carotene in food has the same vitamin A activity as 1 mg retinol (21).

INDICATIONS AND USAGE

Food Sources

β -Carotene is the most widely studied carotenoid and is one of the major carotenoids in our diet and in human blood and tissues (22,23). Major sources of dietary β -carotene include green leafy vegetables as well as orange and yellow fruits and vegetables (Table 1) (24). However, the bioavailability of β -carotene from green leafy

Table 1 β-Carotene Content of Foods (24)

Food	Content (mg/100 g wet weight) ^a
Carrots, raw	7.9
Carrots, cooked	9.8
Apricots, raw	3.5
Apricots, dried	17.6
Cantaloupe, raw	3.0
Kale	4.7
Pepper, red	2.2
Pumpkin	3.1
Spinach, raw	4.1
Spinach, cooked	5.5
Sweet potato, cooked	8.8
Winter squash, cooked	2.4

^aEdible portion.

vegetables such as spinach is thought to be low with a conversion factor of carotene to retinol of 20:1, whereas the conversion factor from fruit may be somewhat better (on the order of 12:1) (25). As discussed above, factors other than food vehicle are thought to be important in the bioavailability of β-carotene. These include cooking, chopping, and the presence of dietary fat, all of which improve the bioavailability (17,26). Of the 50 different carotenoids that can be metabolized into vitamin A, β-carotene has the highest provitamin A activity. Genetically engineered “Golden Rice” contains up to 35 μg of β-carotene per gram rice (27), with a the conversion factor of Golden Rice β-carotene to retinol in adults of 3.8:1, with a range of 1.9–6.4:1 by weight. Typical dietary intakes of β-carotene in the United States are 0.5 to 6.5 mg/day (28–30). However, intakes much higher than this are possible through over-the-counter supplements, which are commonly available in health food stores in doses of 3 to 20 mg/capsule.

Recommended Intakes

Although at present no dietary reference intakes (DRIs) are proposed for β-carotene, existing recommendations for increased consumption of carotenoid-rich fruits and vegetables are supported. Based on the evidence that β-carotene supplements have not been shown to provide any benefit for the prevention of major chronic diseases and may cause harm in certain subgroups (e.g., smokers and asbestos workers), it is concluded that β-carotene supplements are not advisable other than as a source of provitamin A. If there is adequate retinol in the diet, there are no known clinical effects of consuming diets low or moderate in β-carotene. β-Carotene is widely used in vitamin and mineral supplements at levels ranging from 0.4 to 20 mg/day. It is given medicinally in doses of up to 6 mg/day for dietary deficiency of vitamin A (although preformed vitamin A is usually used for this purpose) and up to 300 mg/day for the reduction of photosensitivity in individuals with erythropoietic protoporphyria.

Although no safe upper level of intake for β-carotene has been established in the United States, the European Expert Group on Vitamins and Minerals has established a safe upper level of β-carotene intake of 7 mg/day (31). The safe upper level applies only to the general population, that is, nonsmokers and those not exposed to asbestos and to β-carotene supplements only, given that there is no

evidence to suggest that β-carotene intake from foods are harmful.

Excessive dietary intake of preformed vitamin A has been associated with reduced bone mineral density and increased risk of hip fractures. β-Carotene may be a safe source of vitamin A in osteoporotic subjects, given that it is not associated with bone demineralization (32).

Cancer Prevention

Observational epidemiologic studies have been very consistent in showing that people who consume higher dietary levels of fruits and vegetables have a lower risk of certain types of cancer (33). The consistency of the results is particularly strong for lung cancer, in which carotenoid and/or fruit and vegetable intake has been associated with reduced risk in all of 8 prospective studies and in 18 of 20 retrospective studies (34). However, in three large randomized clinical trials using high-dose β-carotene supplements (20 mg/day, 30 mg/day, or 50 mg given every other day for 4–12 years), no protection was reported with respect to lung cancer or any other cancer (1,2,35). In fact, in two of these studies, there was an increased risk of lung cancer in heavy smokers and asbestos workers with β-carotene supplementation (1,2) (see “Contraindications”). More recently, it was reported that longer duration of use of individual β-carotene supplements (but not total 10-year average dose) was associated with statistically significantly elevated risk of total lung cancer (36). However, there was little evidence for effect modification by gender or smoking status.

Cardiovascular Disease

A body of evidence indicating that the oxidation of LDL plays an important role in the development of atherosclerosis has led investigators to consider a preventive role for β-carotene. Early in vitro studies of LDL oxidation showed that β-carotene carried in LDL is oxidized before the onset of oxidation of LDL polyunsaturated fatty acids, suggesting a possible role in delaying LDL oxidation. Epidemiologic studies, including descriptive, cohort, and case-control studies, suggest that β-carotene-rich diets are associated with a reduced risk of cardiovascular disease (37–39). Furthermore, inverse association between serum or adipose β-carotene levels and cardiovascular outcomes has also been observed. However, in a meta-analysis of eight β-carotene treatment trials involving 138,113 subjects, a dose range of 15 to 50 mg/day and follow-up range from 1.4 to 12.0 years, it was found that β-carotene supplementation led to a small but significant increase in all-cause mortality and a slight but significant increase in cardiovascular death (40).

Erythropoietic Protoporphyria

Erythropoietic protoporphyria is an inborn defect of ferrochelatase resulting in an increase in the protoporphyrin content of the erythrocytes, plasma, and feces. The disease is characterized clinically by photosensitivity, which generally appears within the first few years of life. These patients experience a burning sensation of the skin within a few minutes or hours of exposure to sunlight, followed by edema, erythema, and purpura. β-Carotene has been used therapeutically for the treatment of erythropoietic

Table 2 β -Carotene Supplementation Trials: Study Designs

Study (Ref.)	Population	Intervention	Duration (yr)
ATBC (2)	29,133 Finnish male smokers (50–69 yr of age)	β -Carotene, 20 mg/day; vitamin E, 50 mg/day	5–8
CARET (1)	18,314 men and women and asbestos workers (45–74 yr of age)	β -Carotene, 30 mg/day; vitamin A, 25,000 IU	<4
PHS (35)	22,071 male physicians (40–84 yr of age)	β -Carotene, 50 mg on alternate days	12
Linxian (42)	29,584 men and women, vitamin and mineral deficient (40–69 yr)	β -Carotene, 15 mg/day; selenium, 50 mg/day; α -tocopherol, 30 mg/day	5

protoporphyrin (41). This is based on the observation that carotenoids prevent photosensitivity in bacteria. On treatment of the condition with extremely high doses (up to 300 mg/day) of β -carotene, a marked improvement in skin photosensitivity has been reported in some, but not all, patients. No toxic effects have been in the limited number of patients reported.

CONTRAINDICATIONS

The epidemiologic observations of possible protective effects of high dietary (not supplemental) β -carotene intakes against cancer, along with what is known about carotenoid biochemical functions, has led to further study of the effect of β -carotene on cancer risk. Long-term large randomized intervention trials were designed to test the efficacy of high doses of β -carotene (20–30 mg/day) in the prevention of cancer (Table 2). As stated above, the results from two trials provided possible evidence of harm from β -carotene supplements in relation to cancer among high-risk individuals, such as smokers and asbestos workers (1,2), but no effect (either beneficial or detrimental) in a generally well-nourished population (34). Moreover, in the Linxian (Chinese) Cancer Prevention Study (42), it was found that supplementation with β -carotene doses, vitamin E, and selenium led to a significant reduction in total mortality (9%), especially from cancer (13%) and particularly stomach cancer (21%) (Table 3). The positive results of the Chinese study probably reflect the correction of a vitamin A deficiency in this study population. A number of mechanisms have been proposed to account for the association between β -carotene supplementation and lung cancer in smokers and asbestos workers, including an imbalance of other carotenoids or antioxidants, a pro-oxidant activity of β -carotene at the high oxygen tensions found in the lungs, induction of P450 enzymes, and the production of damaging β -carotene oxidation products by components of cigarette smoke (3).

The epidemiologic studies that led to these intervention studies reported an inverse relationship between diet

and/or blood β -carotene levels and cancer prevention. It is probable that β -carotene serves as a marker of increased fruit and vegetable intake and, therefore, of all components that have cancer prevention potential, for example, vitamin C, folic acid, other carotenoids, and polyphenols. Alternatively, low-dose dietary levels could have a protective effect against cancer, whereas high-dose supplement β -carotene could have a cancer stimulating effect.

TOXICITY/ADVERSE EFFECTS

β -Carotene obtained from eating fruits and vegetables is considered safe. β -Carotene first became available as a pharmaceutical product in the early 1970s. It can be purified from natural sources such as green plants or algae, or it can be manufactured synthetically. Purity of β -carotene may be a problem when derived from plant or algal sources. Preparations of crystalline β -carotene in oil are widely available. Although not harmful, high doses of β -carotene (from foods and supplements) can result in a skin condition known as carotenodermia, in which the skin turns to yellow–orange color due to an elevation of plasma and tissue carotene concentrations. Carotenodermia is reversible when β -carotene ingestion is discontinued. This condition has been reported in adults taking supplements containing 20 to 30 mg/day or more of β -carotene for long periods of time or consuming high levels of carotenoid-rich foods such as carrots (43) and is the primary effect of excess carotenoid intake noted in infants, toddlers, and young children (44). Carotenodermia is distinguished from jaundice in that the ocular sclerae are yellowed in jaundiced subjects but not in those with carotenodermia.

In the treatment of erythropoietic protoporphyria (180 mg/day), no toxic effects have been observed for very high doses of β -carotene (41). However, the number of patients studied has been small. There is no evidence that β -carotene is teratogenic, mutagenic, or carcinogenic in long-term bioassays in experimental animals (45). In humans, there have been no reports of reproductive toxicity or teratogenicity associated with high β -carotene intake, either before or during pregnancy. In addition, long-term supplementation with β -carotene to persons with adequate vitamin A status does not increase the concentration of serum retinol, as the metabolic conversion is regulated by vitamin A status, that is, the better the vitamin A status, the lower the conversion to vitamin A (20).

Doses of 20 to 30 mg/day of β -carotene for 4 to 12 years have been associated with an increased risk of lung cancer in high-risk groups (i.e., smokers and asbestos-exposed workers). Similar to the results in human

Table 3 β -Carotene Supplementation Trial: Cancer Outcomes

Study (Ref.)	Cancer outcome
ATBC (2)	18% increase in lung cancer; 8% increase in mortality
CARET (1)	28% increase in lung cancer; 17% increase in deaths
PHS (35)	No effect of supplementation on incidence of cancer
Linxian (42)	13% decrease in total cancers; 9% decrease in overall deaths

intervention studies, β -carotene supplementation for several months (at doses equivalent to a 30-mg dose in man) to ferrets exposed to cigarette smoke resulted in the development of squamous cell metaplasia in the lungs of ferrets (46). The development of squamous cell metaplasia was also observed in animals supplemented with β -carotene (at the same dose as above) without exposure to smoke, although the metaplasia was less prominent. Whether high, chronic doses of β -carotene in low-risk groups, for example, nonsmokers, would have toxic effects is not known at this time.

COMPENDIAL/REGULATORY STATUS

β -Carotene is in the generally recognized as safe (GRAS) list issued by the Food and Drug Administration.

Carotenoids Overview

Elizabeth J. Johnson and Robert M. Russell

INTRODUCTION

Carotenoids are a family of compounds of over 600 fat-soluble plant pigments, which provide much of the color seen in nature. For example, carotenoids are responsible for the red color of tomatoes and the orange color of carrots. Apart from their aesthetic role, carotenoids are considered to be beneficial in the prevention of various diseases, including certain cancers and eye disease. The beneficial effects of carotenoids are attributed to a small portion of the hundreds of carotenoids found in nature, given that only about two dozen are found in human blood and tissue, and only two in the eye. The carotenoids that have been most studied in this regard are α -carotene, β -carotene, cryptoxanthin, lycopene, lutein, and zeaxanthin. (See also separate chapters on " β -Carotene," "Lutein," and "Lycopene.") β -Carotene and lycopene belong to a class of carotenoids called carotenes and are highly fat soluble. Cryptoxanthin, lutein, and zeaxanthin belong to a class of carotenoids called xanthophylls. Because xanthophylls contain at least one hydroxyl group, they are more polar than that of carotenes. Thus, α -carotene, β -carotene, and lycopene tend to predominate in low-density lipoproteins (LDL) in the circulation, whereas high-density lipoproteins (HDL) are major transporters of cryptoxanthin, lutein, and zeaxanthin (1). In part, the protection against chronic disease by carotenoids is thought to be through their antioxidant activity. Lutein and zeaxanthin are thought to have an additional protective role of absorbing damaging blue light that enters the eye.

FOOD SOURCES

The most common carotenoids in the U.S. diet are α -carotene, β -carotene, β -cryptoxanthin, lycopene, lutein, and zeaxanthin (2). Rich sources of α - and β -carotene include carrots and winter squashes. Foods high in β -cryptoxanthin are orange and red fruits and vegetables such as pumpkin, papayas, and red peppers. Tomatoes account for approximately 80% of the dietary lycopene (3). Dark green leafy vegetables such as spinach and kale are rich sources of lutein and zeaxanthin. The relatively low bioavailability of carotenoids from foods is, in part, due to their association with proteins in the plant matrix (4). Disruption of the plant matrix with chopping, blending, or cooking can increase carotenoid bioavailability (5).

ABSORPTION AND METABOLISM

Carotenoids, being fat soluble, follow the same intestinal absorption path as dietary fat. Carotenoids are released

from food matrices and solubilized in the gut. This is done in the presence of fat and conjugated bile acids. As little as 3 to 5 g of fat in a meal is sufficient for carotenoid absorption (5,6). Absorption is affected by the same factors that influence fat absorption. Thus, the absence of bile or any generalized malfunction of the lipid absorption system (e.g., small intestinal disease, pancreatic disease) will interfere with the absorption of carotenoids. Chylomicrons are responsible for the transport of carotenoid from the intestinal mucosa to the bloodstream via the lymphatics for delivery to tissues. Carotenoids are transported in the plasma exclusively by lipoproteins, being carried predominantly by LDL (carotenes) and HDL (xanthophylls) (7). The delivery of carotenoids to extrahepatic tissues is accomplished through the interaction of lipoprotein particles with receptors and the degradation of lipoprotein lipase.

Plant sterols reduce the absorption of cholesterol in the gut, in part by competing with cholesterol when they are incorporated into the mixed micelles (8). Stanol and steryl esters reduce plasma concentrations of carotenoids (9,10). It is thought that, during the absorption process in the intestine, plant sterols could displace not only cholesterol but also these lipophilic molecules and replace them in incorporation into mixed micelles.

BIOLOGICAL ACTIVITIES

To date, the only known essential function of carotenoids is as a source of vitamin A. The carotenoids in this category are α -carotene, β -carotene, and β -cryptoxanthin (11). The vitamin A activity of β -carotene in food is 1/12 that of vitamin A (retinol), and vitamin A activity of both α -carotene and β -cryptoxanthin is 1/24 that of vitamin A (11).

Most carotenoids have antioxidant activity. β -Carotene and others carotenoids have antioxidant properties as shown in in vitro and animal models. Mixtures of carotenoids or associations with others antioxidants (e.g., vitamin E) can increase their activity against free radicals (12). The use of animal models for studying carotenoids is limited because most of the animals do not absorb or metabolize carotenoids similarly to humans. Epidemiologic studies have shown an inverse relationship between the presence of various cancers and dietary or blood carotenoid levels (13). However, three out of four intervention trials using high-dose β -carotene supplements did not show protective effects against cancer or cardiovascular disease. Rather, the high-risk populations (smokers and asbestos workers) in these high-dose intervention trials showed an increase in cancer and angina cases (14–17).

Figure 1 Structures of the major dietary carotenoids.

Therefore, carotenoids may promote health when taken at dietary levels but may have adverse effects when taken in high dose by subjects who smoke or who have been exposed to asbestos.

The long chain of alternating double and single bonds is a characteristic of all carotenoids (Fig. 1). This feature allows them to absorb light in the visible range of the light spectrum (18). This may be of particular importance in the macula of the retina, where lutein and zeaxanthin are highly concentrated to the exclusion of all other carotenoids (19). In the macula, lutein and zeaxanthin absorb blue light to reduce the amount of light that reaches critical visual structures, thereby providing some protection from light-induced oxidative damage (20).

CONCLUSIONS

Epidemiologic studies support a protective role of carotenoids in the prevention of certain major diseases, including certain cancer and eye disease. The hypothesis that these antioxidant nutrients may protect against certain diseases is plausible, given the putative role of oxidative damage in the etiology of these diseases. However, clinical trials have suggested that supplementation with high dose of β -carotene may have an adverse effect on the incidence of cancer in smokers and workers exposed to asbestos. Current recommendations include diets high in fruits and vegetables, which are rich sources of carotenoids.

Cascara Sagrada

Kapil K. Soni and Gail B. Mahady

INTRODUCTION

Rhamnus purshiana De Candolle is the largest species of buckthorn, occasionally growing up to 15 m in height; however, it is more commonly a large shrub or small tree (5–10 m) (1–5). *Rhamnus purshiana* is native to the Pacific Northwest United States and southwestern Canada (1–5). *Rhamnus* is the generic name for buckthorn, and the species name, *purshiana*, was given in honor of the German botanist Friedrich Pursh (4). The crude drug consists of the dried bark of the tree, which is officially known as Cascara or cascara sagrada, Spanish for “sacred bark” (1–4). The dried aged bark of the tree has been used by Native Americans for centuries as a laxative. It was accepted into medical practice in the United States in 1877 as a commonly used laxative and was the principal ingredient in many over-the-counter (OTC) laxative products. Cascara was first listed in the U.S. Pharmacopeia (USP) in 1890 as a laxative mild enough for use in treating the elderly and children. Products that were official in the USP included cascara sagrada extract, fluidextract, aromatic fluidextract, and tablets. In 2002, the U.S. Food and Drug Administration issued a final rule concerning the status of cascara sagrada (including casanthranol, cascara fluidextract aromatic, cascara sagrada bark, cascara sagrada extract, and cascara sagrada fluidextract) in OTC drug products (5). The final rule stated that cascara sagrada in OTC drug products is not generally recognized as safe and effective or is misbranded (6).

BACKGROUND

General Description

The shrub or small tree of *R. purshiana* De Candolle has elliptical leaves, greenish flowers, and black berries. It ranges in height from 4.5 to 15 m and has a reddish-brown bark (4). Most of the commercial production comes from Oregon, Washington, and southern British Columbia. The bark is collected in spring (April/May) and early summer by stripping from wild trees scattered throughout the native forests. It is removed by making longitudinal incisions and peeling off sections, which tend to roll into large quills. Trees are also felled and the bark is removed from the larger branches. The bark is then air dried, with the inner surface protected from the sun in order to preserve its yellow color. The dried bark is allowed to mature for 1 or 2 years before use in commercial preparations (4). The fresh bark contains chemical constituents that act as a gastrointestinal (GI) irritant and emetic; thus, the bark must be aged for at least 1 year prior to human use. Cascara bark and its preparations have been used for centuries by

the Pacific Northwest Native Americans, as well as the European settlers, and cascara preparations are now used worldwide as a laxative (5).

Commercial preparations of cascara (*Cortex Rhamni Purshianae*) consist of the dried, whole, or fragmented bark of *R. purshiana*. The bark and its preparations are official in the pharmacopeias of many countries (1,7–9). Cascara was first listed in the USP in 1890 as a laxative. The official listing of cascara in USP 25 (9) defined it as the dried bark (at least 1-year old) of *R. purshiana*, yielding not less than 7% of total hydroxyanthracene derivatives calculated as cascaroside A on a dried basis. Not less than 60% of the total hydroxyanthracene derivatives consist of cascarosides, calculated as cascaroside A (9).

CHEMISTRY AND PREPARATION OF PRODUCTS

The chemistry of cascara has been extensively investigated and numerous quinoid constituents are reported to be present in the bark (1). Much of the chemical and pharmacological research on cascara was performed over 50 years ago, and anthraquinone glycosides were established as the active constituents of the bark (5). Hydroxyanthracene glycosides make up 6% to 9% of the bark, of which 70% to 90% is C-10 glycosides, with aloins A and B and desoxyaloins A and B (= chrysaloins) accounting for 10% to 30% (1). The cascarosides A and B and cascarosides C and D are diastereoisomeric pairs derived from 8- β -O-glucosides of aloin A and B and 8-O-glucosyl-11-desoxyaloin, respectively, and constitute 60% to 70% of the total glycosides (1). Hydrolysis of the cascarosides cleaves the O-glycosidic bonds to yield aloins (barbaloin and chrysaloin). The cascarosides are not bitter, whereas most of their hydrolysis products (the aloins) are very bitter. Both the USP and the European Pharmacopoeia recognize the cascarosides and aloins as the active constituents of cascara and have chemical assay procedures for determining these glycosides (7–9).

Other major hydroxyanthracene glycosides include the hydroxyanthraquinones chrysophanol-8-O-glucoside and aloe-emodin-8-O-glucoside at a concentration of 10% to 20% (10). In the fresh bark, anthraquinones are present in the reduced form and are converted by oxidation to their corresponding parent anthraquinone glycosides during drying and storage (3).

Dosage Forms and Dose

Cascara sagrada is available as extracts, fluidextracts, and tablets (9). The average daily dose (taken at bedtime, or

one-half dose in the morning and at bedtime) of standardized preparations is 20 to 30 mg of hydroxyanthracene derivatives calculated as cascarioside A (dried aged bark, 0.25–1 g) (1). Do not exceed the recommended dose and do not use this dose for more than 1 to 2 weeks continuously.

PRECLINICAL STUDIES

Toxicity

While there are no specific data describing the carcinogenicity or mutagenicity for cascara sagrada, there are data available for emodin, one of the naturally occurring anthraquinones present in cascara (11–18). There are several studies reporting genotoxic and mutagenic effects both in vitro and in vivo for emodin and its derivatives, causing them to be classified as potential carcinogens (12–18). In vitro, the toxicity of 1,8-dihydroxyanthraquinones, such as emodin, may involve redox cycling between the quinone and the semiquinone radical generating reactive oxygen species (ROS), resulting in lipid peroxidation, protein damage, and DNA oxidation (16,19,20). For example, treatment of Reuber hepatoma and fibroblast Balb/3T3 cells with various anthraquinones resulted in the formation of 8-oxo-dG (16). In addition, concentrations of 50 μ M aloe-emodin increased DNA damage as measured by the single-cell gel electrophoresis assay (COMET assay) (21). Aloe-emodin and other anthraquinones also dose dependently induced tk-mutations and micronuclei in mouse lymphoma L5178Y cells and inhibited topoisomerase II-mediated decatenation in a DNA decatenation assay (21,22). The authors suggested that anthraquinones bind noncovalently to DNA and inhibit the catalytic function of topoisomerase II, which can lead to DNA breakage by competing with the DNA binding site of the enzyme (23). It is also possible that anthraquinones can covalently bind to DNA as observed with other quinones, such as *p*-benzoquinone (24,25). Binding of anthraquinones to DNA might also facilitate DNA oxidation due to their high potency of generating ROS. Besides the above-mentioned effects of redox cycling by anthraquinones, it is also reported that production of ROS by emodin can cause an immunosuppressive effect in human mononuclear cells and might result in apoptosis in A549 cells in vitro (19).

In vivo toxicology was assessed by the National Toxicology Program and published in 2001 (11). Reports that 1,8-dihydroxyanthraquinone caused tumors in the GI tract of rats led to the investigation of emodin in rodents, as this compound is structurally similar and was reported to be mutagenic in bacteria. The acute and chronic toxicities of emodin were investigated in rodents exposed to emodin in feed for 16 days, 14 weeks, or 2 years. In the 16-day study, rodents were fed diets containing average daily doses equivalent to 50, 170, 480, 1400, or 3700 mg/kg body weight for males and 50, 160, 460, 1250, or 2000 mg/kg body weight for females. The results showed that the mean body weights of males and females exposed to 480 mg/kg or greater were significantly lower than those of the controls. Macroscopic lesions were observed in the gallbladder and kidney of rats exposed to the highest doses of 1400 or 3700 mg/kg. In the 14-week study, rats were fed diets containing approximately 20, 40, 80, 170, or 300 mg/kg for males and females. Mean body

weights of males exposed to 170 mg/kg or greater and females exposed to 80 mg/kg or greater were significantly lower than those of the controls. In rats exposed to 170 or 300 mg/kg of emodin, increases in platelet counts and decreases in total serum protein and albumin concentrations were observed. Relative kidney weights of rats exposed to 80 mg/kg or greater and relative lung and liver weights of rats exposed to 40 mg/kg or greater were significantly increased compared to the control groups. The incidences and severities of nephropathy were increased in males and females exposed to 40 mg/kg or greater. In the chronic toxicity study (2 years), groups of 65 male and 65 female rats were fed diets containing emodin at an equivalent to average daily doses of approximately 110, 320, or 1000 mg/kg to males and 120, 370, or 1100 mg/kg to females for 105 weeks. Survival of exposed males and females was similar to that of the controls. There were negative trends in the incidences of mononuclear cell leukemia in both male and female rats and incidence of leukemia in the group fed 1000 mg/kg was significantly decreased. At the 12-month interim evaluation, nephropathy was slightly higher (11).

In terms of genetic toxicology, emodin was mutagenic in *Salmonella typhimurium* strain TA100 in the presence of S9 activation; however, no mutagenicity was detected in strain TA98, with or without S9 (11). Chromosomal aberrations were induced in cultured Chinese hamster ovary cells treated with emodin, with or without metabolic activation by S9. In the rat bone marrow micronucleus test, administration of emodin by three intraperitoneal injections gave negative results. Results of acute-exposure (intraperitoneal injection) micronucleus tests in bone marrow and peripheral blood erythrocytes of male and female mice were also negative. In a peripheral blood micronucleus test on mice from the 14-week study, negative results were seen in male mice, but a weak positive response was observed in similarly exposed females.

The results of these investigations show no evidence of carcinogenic activity of emodin in male F344/N rats in the two-year study. There was equivocal evidence of carcinogenic activity of emodin in female F344/N rats and male B6C3F1 mice. There was no such evidence in female B6C3F1 mice exposed to 312, 625, or 1250 ppm (11).

Other investigations of the carcinogenic potential of cascara have been carried out in rodents. In one study, the effects of the laxative bisacodyl (4.3 and 43 mg/kg) and cascara (140 and 420 mg/kg) on the induction of azoxymethane (AOM)-induced aberrant crypt foci (ACF) and tumors in rats were investigated (26). Animals were treated with AOM and laxatives (alone or in combination) for 13 weeks. The results demonstrated that bisacodyl (4.3 and 43 mg/kg), given alone, did not induce the development of colonic ACF and tumors. However, bisacodyl (4.3 mg/kg) coupled with AOM increased the number of crypts per focus but not the number of tumors. Bisacodyl (43 mg/kg) significantly increased the number of crypts per focus and tumors. Cascara (140 and 420 mg/kg) did not induce the development of colonic ACF and tumors and did not modify the number of AOM-induced ACF and tumors (27). Results from another study were similar. Dietary exposure to high doses of these glycosides for 56 successive days did not induce the appearance of ACF or increase in incidence of ACF induced by

1,2-dimethylhydrazine (DMH). However, in rats treated with both DMH and the highest dose of glycosides, the average number of aberrant crypts per focus, considered a consistent predictor of tumor outcome, was higher than that in rats given DMH alone (26).

CLINICAL STUDIES

Laxative Effects

Cascara sagrada is an anthraquinone laxative and is used for short-term treatment of occasional constipation (1,28,29). The laxative effects of cascara are primarily due to the anthraquinone glycosides, the cascarosides A–D (1,5). Other anthranoid derivatives that may be active include emodin anthrone-6-O-rhamnoside (franguloside), and physcion and chrysophanol in glycosidic and aglycone forms (30,31). Anthraquinone laxatives are prodrugs in that after oral administration, the hydroxyanthracene glycosides are poorly absorbed in the small intestine, but are hydrolyzed in the colon by intestinal bacteria to form pharmacologically active metabolites, which are partly absorbed there (28,30); this acts as a stimulant and irritant to the GI tract (29).

The mechanism of action of cascara is similar to that of senna in that the action is twofold: (i) stimulation of colonic motility, resulting in augmented propulsion, and accelerated colonic transit (which reduces fluid absorption from the fecal mass); and (ii) an increase in the paracellular permeability across the colonic mucosa, probably due to an inhibition of Na^+ , K^+ -adenosine triphosphatase or an inhibition of chloride channels (30,32), which results in an increase in the water content in the large intestine (29,32). The laxative effect of cascara is generally not observed before 6 to 8 hours after oral administration. The hydroxyanthracene glycosides are excreted predominantly in the feces but are excreted to some extent in urine as well, producing an orange color; anthrones and anthranols also pass into breast milk (30).

Anthraquinone laxatives may produce an excessive laxative effect and abdominal pain. The major symptoms of overdose are gripes and severe diarrhea, with consequent losses of fluid and electrolytes (29). Treatment should be supported with generous amounts of fluid. Electrolytes should be monitored, particularly potassium. This is especially important in children and the elderly. Renal excretion of the compounds may cause abnormal coloration of urine (yellow–brown to reddish depending on the pH of the urine). Large doses may cause nephritis. Melanotic pigmentation of the colonic mucosa (pseudomelanosis coli) has been observed in individuals who abuse anthraquinone laxatives. Pigmentation is usually benign and reverses within 4 to 12 months of discontinuation of the products (29).

Contraindications and Precautions

Patients should be warned that certain constituents of cascara sagrada are excreted by the kidney and may color the urine (harmless). Rectal bleeding or failure to have a bowel movement after the use of a laxative may indicate a serious condition. Laxatives containing anthraquinone glycosides should not be used for periods longer than 1 to 2 weeks (29). Decreased intestinal transit time may result

in reduced absorption of orally administered drugs (1). Electrolyte imbalances such as increased loss of potassium may potentiate the effects of cardiotonic glycosides (e.g., digitalis). Existing hypokalemia resulting from long-term laxative abuse can also potentiate the effects of antiarrhythmic drugs that affect potassium channels to change sinus rhythm, such as quinidine. The induction of hypokalemia by drugs such as thiazide diuretics, adrenocorticosteroids, or liquorice root may be enhanced, and electrolyte imbalance may be aggravated (28).

Chronic use (>2 weeks) may cause dependence and need for increased doses, and an atonic colon with impaired function (29). It may also lead to pseudomelanosis coli (harmless) and to an aggravation of constipation with dependence and possible need for increased dosages. Chronic abuse with diarrhea and consequent fluid and electrolyte losses (mainly hypokalemia) may cause albuminuria and hematuria, and may result in cardiac and neuromuscular dysfunction (1).

Anthraquinone stimulant laxatives, such as cascara, should not be administered to patients with intestinal obstruction and stenosis, atony, severe dehydration states with water and electrolyte depletion, or chronic constipation (1,29). Cascara should not be administered to patients with inflammatory intestinal diseases, such as appendicitis, Crohn disease, ulcerative colitis, and irritable bowel syndrome, or in children younger than 12 years (1,29). As with other stimulant laxatives, cascara is contraindicated in patients with cramps, colic, hemorrhoids, nephritis, or any undiagnosed abdominal symptoms such as pain, nausea, or vomiting (29).

Because of the pronounced action on the large intestine and insufficient toxicological investigations, products containing cascara should not be administered to pregnant women (33,34). Furthermore, anthranoid metabolites are excreted into breast milk. Thus, cascara should not be used during lactation, due to insufficient data available to assess the potential for pharmacological effects in the breast-fed infant (33).

Adverse Reactions

In single doses, cramp-like discomfort of the GI tract may occur, which may require a reduction of dosage. Overdose can lead to colicky abdominal spasms and pain, as well as the formation of thin, watery stools. Long-term laxative abuse may lead to electrolyte disturbances (hypokalemia, hypocalcemia), metabolic acidosis, malabsorption, weight loss, albuminuria, and hematuria (35,36). Weakness and orthostatic hypotension may be exacerbated in elderly patients when stimulant laxatives are used repeatedly. Secondary aldosteronism may occur due to renal tubular damage after aggravated use. Steatorrhea and protein-losing gastroenteropathy with hypoalbuminemia have also been reported in laxative abuse (36). Melanotic pigmentation of the colonic mucosa (pseudomelanosis coli) has been observed in individuals taking anthraquinone laxatives for extended time periods (29,36–39). The pigmentation is clinically harmless and usually reversible within 4 to 12 months after the drug is discontinued (36–40). Conflicting data exist on other toxic effects such as intestinal–neuronal damage after long-term use (36). Use of the fresh drug may cause severe vomiting,

with possible spasms (30). Cases of allergic respiratory diseases after occupational exposure to cascara have been reported (41). Cascara sagrada is an etiologic agent of IgE-mediated occupational asthma and rhinitis. One case of cholestatic hepatitis, complicated by portal hypertension, has been attributed to the ingestion of cascara in one patient who was also known to abuse alcohol and take a number of other prescription medications (42).

CURRENT REGULATORY STATUS

Prior to June 1998, cascara sagrada was recognized by the Food and Drug Administration (FDA) as a category I (safe and effective) OTC preparation (monograph). In 2002, the U.S. FDA issued a final rule concerning stimulant laxatives including cascara sagrada (including casanthranol, cascara fluidextract aromatic, cascara sagrada bark, cascara sagrada extract, and cascara sagrada fluidextract) in OTC drug products, stating that they are not generally recognized as safe and effective or are misbranded (6). This final rule was based on a decision made by the agency after it had requested mutagenicity, genotoxicity, and carcinogenicity data on cascara in 1998. No comments or data were provided to the FDA for cascara; thus on the basis the lack of data and information and the failure of any persons to submit new data from carcinogenicity studies, the agency has determined that these laxative should be deemed not generally recognized as safe and effective for OTC use and has thus reclassified these ingredients to category II (nonmonograph) (6). According to the FDA, products containing aloe and cascara sagrada ingredients must be reformulated or discontinued; the stimulant laxatives must therefore be deleted or replaced. Reformulated products will also need to be relabeled. This final rule is part of FDA's ongoing OTC drug product review. However, these products may still be sold as dietary supplements under the Dietary Supplements Health and Education Act of 1994.

Chaste Tree

Gail B. Mahady, Joanna L. Michel, and Kapil K. Soni

INTRODUCTION

Vitex agnus castus L. (Verbenaceae), commonly referred to as chaste tree or chasteberry, is a small shrubby tree, approximately 1 to 6 m in height and native to the Mediterranean region and Asia (1,2). The tree is also widely cultivated in warm temperate regions of the world. The name “chasteberry” may be derived from the traditional belief that the plant promoted chastity (3). The fruits of *V. agnus castus* (VAC) were used in ancient Greece and Rome, as well as by the monks of the Middle Ages, to suppress sexual desire (4,5). In the past, extracts of VAC have been used for the treatment of gynecological disorders, such as endometrial hyperplasia, hypermenorrhea, and secondary amenorrhea, as well as endocrine-dependent dermatoses (dermatitis dysmenorrhea symmetrica, acne vulgaris, eczema, and acne rosacea) (6–8).

Today, extracts of the dried ripe fruits of VAC are regulated in the United States as dietary supplements under the 1994 Dietary Supplement Health and Education Act. They are widely used as a botanical dietary supplement for the management of gynecological disorders including corpus luteum insufficiency (9,10), premenstrual syndrome (PMS) (11–13), menstrual problems (14,15), cyclic mastalgia (16–18), as well as to treat hormonally induced acne (19). In addition, VAC has been traditionally used to treat fibroid cysts and infertility, stop miscarriages caused by progesterone insufficiency (20), and treat indigestion (3).

CHEMISTRY AND PREPARATION OF PRODUCTS

Commercial products of VAC are prepared from the dried, ripe fruit, containing not less than 0.4% (v/w) of volatile oil and at least an 8% water-soluble extractive (1,21). To date, although the active constituents of VAC remain unknown, the European Pharmacopoeia recommends a minimum content of 0.08% casticin in the dried plant material (22). Two compounds are currently used as marker compounds for quality control: the iridoid glycoside *agnuside* and the flavonol *casticin* (23). Most VAC preparations used in European medicine are nonstandardized fluid extracts, tinctures, and/or native dry extracts. The “native” or “total” extract is an approximate 10:1 (w/w) drug-to-extract ratio containing 0.6% to 1.0% casticin (2).

The ripe, dried VAC fruit yields 0.4% to 0.7% (v/w) essential oil, depending on distillation time and comminution size. The oil is mainly composed of bornyl acetate, 1,8-cineole, limonene, α - and β -pinene, β -caryophyllene, and α -terpinyl acetate (24). Flavonoids,

iridoids, and diterpenes represent major groups of secondary constituents that are also found in the fruit (2). Casticin (up to 0.2%) is considered to be the major flavonoid, with chrysopenetin, chrysosplenol D, cynaroside, 5-hydroxy-3,4',6,7-tetramethoxyflavone, 6-hydroxykaempferol, isorhamnetin, luteolin, and luteolin 6-C-glycoside derivatives being other compounds of this class (24–26). Major iridoids found include agnuside (*p*-hydroxybenzoylaucubin, 0.0014%) and aucubin (0.0013%). Diterpene constituents include vitexilactone (0.001–0.004%), 6 β ,7 β -diacetoxy-13-hydroxylabda-8,14-diene, rotundifuran, vitexlabdines A–D, and vitexlactam A (24,25). The structures of the above-mentioned components are presented in Figure 1.

PRODUCTS AND DOSAGE

There is a wide range of VAC extracts and products available to consumers. The following examples are a general list of products used in clinical trials and listed in reference texts. This list is not complete and is not intended as a recommendation of one product over another. The dose as listed is intended for adults, and the products are not recommended for children.

- Dry native ethanolic extracts, 8.3–12.5:1 (w/w), approximately 1.0% casticin: one tablet, containing 2.6 to 4.2 mg native extract. The tablets should be swallowed whole with some liquid each morning.
- Dry native extract, 9.58–11.5:1 (w/w): one tablet containing 3.5 to 4.2 mg native extract each morning with some liquid (27).
- Dry native extract, 6.0–12.0:1 (w/w), approximately 0.6% casticin: PMS: one tablet containing 20 mg native extract daily with water upon awaking or just before bedtime, before meals.

Figure 1 Compounds from *Vitex agnus castus* fruits.

- Fluid extract: 1:1 (g/mL), 70% alcohol (v/v): 0.5 to 1.0 mL.
- Fluid extract: 1:2 (g/mL): 1.2 to 4.0 mL.
- Tinctures, alcohol 58 vol% (100 g of aqueous-alcoholic solution contains 9 g of 1:5 tincture): 40 drops, one time daily with some liquid each morning.
- Tinctures, ethanol 19% (v/v) (100 g of aqueous-alcoholic solution contains 0.192–0.288 g extractive corresponding to 2.4 g dried fruit): 40 drops, once daily.
- Hydroalcoholic extracts (50–70%; v/v): corresponding to 30 to 40 mg dried fruit (2,28).

CLINICAL STUDIES

Extracts from VAC fruits are primarily used for the symptomatic management of corpus luteum insufficiency, hyperprolactinemia (9,10), PMS (11–13,24,27,29), and cyclic mastalgia (16–18). A few clinical studies have also indicated that VAC may also be a potential treatment for infertility due to hyperprolactinemia and luteal-phase defect (30), insufficient lactation, as well as to prevent miscarriages due to progesterone insufficiency (20).

Since the 1950s, over 35 human or clinical studies have assessed the safety and efficacy of various VAC extracts and tinctures (53–70% ethanol) for the treatment of acne, corpus luteum insufficiency, cyclic breast pain, hyperprolactinemia, menopausal symptoms, increasing lactation, PMS, uterine bleeding disorders, and miscellaneous menstrual irregularities. Most of these investigations are open, uncontrolled studies assessing the effects of VAC for the management of menstrual cycle irregularities or PMS. The results from randomized, controlled clinical trials are also published.

Premenstrual Syndrome

PMS refers to the regular occurrence of affective symptoms, such as depressive moods, irritability, anxiety, confusion, and social withdrawal, as well as somatic symptoms including breast tenderness or heaviness and breast pain (mastalgia), abdominal bloating, cravings, fatigue, and headache (31). The syndrome affects approximately 30% to 40% of menstruating women and is one of the most frequent complaints noted in gynecology practice (27). Approximately 13 clinical trials have assessed the safety and efficacy of VAC extracts for the symptomatic treatment of PMS (11,12,14,27,29,32–39). Of these investigations, only three were randomized, controlled trials and two were double blinded (27,36–39).

The most recent clinical trial assessing the safety and efficacy of VAC for the management of PMS was a prospective, randomized, multicenter placebo-controlled trial in Chinese women (39). After the screening and preparation phase lasting three cycles, eligible patients were randomly assigned into treatment or placebo groups and were treated with a VAC extract daily or placebo for up to three cycles. Efficacy was assessed using the Chinese version of the PMS-diary (PMSD) and Premenstrual Tension Syndrome (PMTS) scale. Two hundred and seventeen women were eligible to enter the treatment phase and were randomly assigned into the treatment group ($n = 108$) or the placebo group ($n = 109$), of these 208 provided the efficacy data (treatment: $n = 104$, placebo: $n =$

104) and 202 completed the treatment phase (treatment: $n = 101$, placebo: $n = 101$). The mean total PMSD scores decreased from 29.23 at baseline (0 cycle) to 6.41 at the termination (3rd cycle) for the treatment group and from 28.14 at baseline (0 cycle) to 12.64 at the termination (3rd cycle) for the placebo group. The total PMSD score of the 3rd cycle was significantly lower than the baseline in both groups ($P < 0.0001$). The difference in the mean scores from the baseline to the 3rd cycle in the treatment group (22.71 ± 10.33) was significantly lower than the difference in the placebo group (15.50 ± 12.94 ; $P < 0.0001$). Results of PMTS were similar in that the total scores for PMTS were significantly lower between the two groups ($P < 0.01$) and within each group ($P < 0.01$). The score was decreased from 26.17 ± 4.79 to 9.92 ± 9.01 for the treatment group and from 27.10 ± 4.76 to 14.59 ± 10.69 for the placebo group. A placebo effect of 50% was found in the present study. No serious adverse events were reported in either group. The study concluded that VAC was well tolerated and was efficacious for the treatment of severe PMS in Chinese women (39).

In a randomized, placebo-controlled study published by Schellenberg et al., women with PMS symptoms were randomized for treatment to either a VAC extract ($n = 86$; one tablet daily) or a placebo ($n = 84$) for three consecutive menstrual cycles (37). A PMS diagnosis was made according to the *Diagnostic and Statistical Manual for Mental Disorders* (DSM-III). The main efficacy variable measured was the change from baseline to the endpoint (end of cycle 3) in the patient's self-assessment (PSA) of six PMS symptoms (irritability, mood alteration, anger, headache, breast fullness, and other indications including bloating). The secondary efficacy variable measured was a change in the Clinical Global Impressions (CGI) score for the severity of condition, global improvement, and risk/benefit ratio. Mean improvement in PSA was significantly greater in the treatment group compared with placebo group ($P < 0.001$). CGI scores for each of the three factors also revealed significant superiority of the treatment relative to placebo ($P < 0.001$). The observed response rate ($> 50\%$ reduction in symptoms) was 52% and 24% for the treatment and placebo groups, respectively. Adverse events reported included treatment ($n = 4$): acne, multiple abscesses, intermenstrual bleeding, urticaria; placebo ($n = 3$): acne, early menstrual period, and gastric upset (37).

A randomized, double-blind, placebo-controlled trial involving 217 women with self-diagnosed PMS assessed the efficacy of the fruit in treating the syndrome. The self-diagnosis was made according to a modified version of the Menstrual Distress Questionnaire (MDQ), a rating scale covering most of the important PMS symptoms (38). Subjects were treated with either a powder of VAC (300 mg tablets; two tablets three times daily; $n = 105$) or a soy-based placebo ($n = 112$) for a period of three months, after which they all completed the modified MDQ again. Other than a statistically significant difference in effect between the VAC powder and the soy-based placebo for the symptom of "feeling jittery and restless" ($P = 0.05$), no other significant results were reported (38). Unfortunately, soy was a poor choice for a placebo in this study, as it is not considered to be biologically inert.

A multicenter, randomized, double-blind, controlled clinical trial compared the activity of a dried

ethanol extract of VAC fruit with that of pyridoxine (vitamin B₆) treatment of women with PMS (27). The intent-to-treat population included 127 women: 61 subjects were given one capsule of extract plus one placebo capsule daily for three cycles, whereas 66 were given one capsule of placebo twice daily on days 1–15 of their cycle, followed by one capsule (100 mg) of pyridoxine twice daily on days 16–35. Therapeutic response was assessed by using the PMTS scale, the CGI scale, and by recording six characteristic symptoms of PMS (breast tenderness, edema, inner tension, headache, constipation, and depression). Therapeutic efficacy was assessed by both patients and physicians, at the end of the trial. Initial mean PMTS scores were higher in the chaste tree group (15.2) compared with the pyridoxine group (11.9). By the end of therapy, the mean absolute change in PMTS score in each group was 5.1, representing a reduction of 10.1 and 6.8 for the chaste tree and pyridoxine groups, respectively ($P < 0.038$, both groups, 95% CI: -6.4261 to -0.1670). Therefore, no difference could be found between the two treatment groups. The CGI scale showed that 77.1% (chasteberry) and 60.6% (pyridoxine) of patients showed improvement. Adverse events were rare but included gastrointestinal complaints, skin reactions, and transient headache (27).

Six postmarketing studies assessed the safety and efficacy of various extracts of the fruit in 8391 female patients with menstrual abnormalities or PMS symptoms (11,14,29,33,34,36). Three open (uncontrolled) studies also assessed efficacy (12,32,35). The dose used ranged from 40 to 42 drops or one capsule daily, for 1 day to 9 years, and the outcomes measured included the physician's assessment and PSA. Elimination of symptoms was observed in 29% to 42% of patients, improvement in 51% to 59%, and no change in 1% to 10%. Adverse events were reported in 1% to 5% of patients but were generally not stated to be serious. The difficulty with these studies includes the lack of a control group, besides most of them not distinguishing between PMS and other menstrual disorders (12,32,35).

An open (uncontrolled) clinical trial involving 50 women (43 completed) with late-luteal phase dysphoric disorder (DSM-III) assessed the effect of an ethanol fruit extract on the management of PMS (32). Thirteen of the subjects were concurrently taking oral contraceptives. After two months of baseline observation, one tablet of the extract was administered daily for three cycles, followed by a posttreatment phase that lasted three cycles. Treatment effectiveness was evaluated using both the MDQ and the visual analogue scale (VAS). The MDQ was filled out by patients at the end of the first cycle and during cycles 3 and 6. The VAS was completed twice per cycle, once in the late-luteal phase when symptoms peaked and the other after menstruation during the follicular phase. By the end of the third cycle, the MDQ scores were reduced by 42.5% ($P < 0.001$), with a 50% reduction in the score in 20/43 patients. By the end of the posttreatment period, the scores remained approximately 20% below baseline ($P < 0.001$). The main symptoms that improved following treatment were breast tenderness, behavioral changes, negative feelings, and edema. The average late-luteal phase VAS score was reduced by 47.2% during the three-month treatment phase ($P < 0.01$) and remained at 21.7% below baseline ($P < 0.001$) during the posttreatment phase. By contrast, the follicular phase score did not significantly change. The

number of days with PMS symptoms was reduced from 7.5 to 6 days ($P < 0.001$), and the concomitant use of oral contraceptives had no significant effect on any of the parameters investigated. Twenty patients (47%) reported 37 adverse events during the treatment and posttreatment periods (32).

An open (uncontrolled) study involving 36 women with PMS assessed the effect of a 58% ethanol extract of the fruit for the management of PMS symptoms (12). The subjects were treated with 40 drops of the extract daily over three cycles and the outcomes measured were a reduction in physical symptoms such as headache, swollen breasts, breast tenderness, bloating, fatigue, and psychological changes such as increased appetite, sugar craving, nervousness and restlessness, anxiety, irritability, lack of concentration, depression, crying spells, mood changes, and aggressiveness. The duration of the luteal phase was also determined. After three months of treatment, 69% of women had a reduction in physical symptoms, where 80% showed a decrease in psychological symptoms ($P < 0.05$). The duration of the luteal phase lengthened from 5.4 to 11.4 days (12).

Mastalgia

Breast pain (mastalgia) is a common complaint and is usually classified as cyclical (associated with the menstrual cycle) or noncyclical (not related to the menstrual cycle). Mild premenstrual breast discomfort, lasting for one to four days prior to menstruation that resolves upon initiation, is considered cyclic mastalgia and is a symptom of PMS. In addition to the experiments reported above, a number of open studies (40–45) and four randomized-controlled clinical trials (16,17,39,46) have assessed the safety and efficacy of VAC extracts for the treatment of cyclic mastalgia.

A randomized, double-blind, placebo-controlled clinical trial involving 104 women with cyclic breast pain (for at least three cycles) assessed the efficacy of a VAC tincture (10 g tincture containing 2 g of crude drug in 53% ethanol VAC) for treatment of the pain (46). The patients were treated with placebo, VAC tincture (30 drops twice daily), or VAC tablets (one tablet twice daily) for three cycles. The subjects assessed the intensity of breast pain once per cycle using a VAS and recorded the presence of menstrual bleeding and the intensity of pain in a diary. Prolactin levels were measured during the premenstrual week of cycles 1 and 3. At the end of the third treatment cycle, a significant reduction in breast pain was observed in the treated patients as compared with placebo (VAC solution, $P = 0.006$; VAC tablets, $P = 0.007$). A significant decrease in prolactin levels ($P = 0.039$) was also noted in the treatment groups as compared with placebo (46).

A second randomized, placebo-controlled, double-blind study with a similar design compared VAC solution (30 drops twice daily for three cycles) with placebo in the treatment of 100 women (50 per group) who had breast pain at least five days prior to menses in the last cycle before the study (16). The treatment phase lasted three menstrual cycles (2×30 drops/day = 1.8 mL of VAC or placebo). Mastalgia for at least five days of the cycle before the treatment was the strict inclusion condition. For assessment of the efficacy, VAS was used. Altogether

97 patients were included in the statistical analysis (VAC: $n = 48$, placebo: $n = 49$). Intensity of breast pain diminished quicker in the VAC group. This study design and duration were similar to that of Wuttke et al. (46). The results of this experiment showed a decrease in the VAS scores in both the treatment and the placebo groups. However, as compared with the placebo, the treatment group had significantly lower VAS values at the end of each cycle ($P = 0.018$, 0.006 , and 0.064 for cycles 1, 2, and 3, respectively).

In a randomized, placebo-controlled trial, the effects of VAC solution and placebo (double-blind) were compared with that of gestagen (Lynestrenol®) in 160 women with mastalgia (18). A complete remission or improvement of symptoms was reported in 82.1%, 74.5%, and 36.8% of the patients in the Lynestrenol, VAC, and placebo groups, respectively. The difference in effect between treatment groups and placebo was significant ($P < 0.01$), but no significant discrepancy was found between the two treatment groups (18).

Open studies have been used to assess the effectiveness of VAC solution for the treatment of over 1700 women with mastalgia (40–45). All these investigations assessed the efficacy of one VAC solution, at a dose of 45 to 75 drops per day for 1 to 6 cycles. Two of these studies compared VAC treatment with Lynestrenol (5 mg daily on days 12–24 of each cycle). Elimination of symptoms was observed in 46% to 81.5% of the treated women, improvement in 12% to 39.6%, and no effect in 6.5% to 29%. Collective reported adverse events from these studies included circulatory disturbances, acne, and weight gain (40–45).

Menstrual Cycle Irregularity and Infertility

Since 1954, at least 17 investigations have assessed the efficacy of VAC extracts for the treatment of menstrual cycle disorders including amenorrhea, oligomenorrhea, polymenorrhea, corpus luteum insufficiency, and infertility (2). Two double-blind placebo-controlled clinical trials and several observational studies have investigated the effect of various fruit extracts on corpus luteal-phase dysfunction and infertility (10,30,47). The products tested were ethanol extracts (53–70% ethanol), and the dose administered was 20 drops twice daily, 15 drops three times daily, 30 drops twice daily, or one to two tablets or capsules daily.

In the first randomized, double-blind, placebo-controlled trial, the efficacy of a dried VAC fruit extract was assessed in infertile women (10). The objective of this study was to determine whether elevated pituitary prolactin levels could be reduced by treatment with VAC, and whether the deficits observed in the luteal-phase length and luteal-phase progesterone synthesis could be normalized. Blood was obtained for hormone analysis on days 5, 8, and 20 of the menstrual cycle, both before and after three months of VAC therapy. Latent hyperprolactinemia was analyzed by monitoring prolactin release 15 and 30 minutes after intravenous administration of 200 µg of thyroid hormone. Thirty-seven cases (placebo: $n = 20$, treatment: $n = 17$) were included in the statistical analysis. After three months of treatment, prolactin release was reduced, a significant increase in the length of the luteal phase (10.5 days; $P < 0.05$) was observed and deficits in luteal pro-

gesterone synthesis were decreased. These changes only occurred in the treatment group and were not observed in the placebo group. All other hormonal parameters did not change with the exception of 17β-estradiol, which was observed to increase during the luteal phase in the treatment group. The overall length of the menstrual cycles did not change, suggesting that there was a corresponding shortening of the follicular phase. Two women in the extract group became pregnant by the end of the study. No adverse events were reported (10).

In a second randomized, double-blind, placebo-controlled trial, the efficacy of a VAC fruit extract was assessed in 96 infertile women (30). The outcome criteria measured included pregnancy or menstrual bleeding in women with secondary amenorrhea or improved luteal hormone concentrations. The subjects were administered 30 drops of the extract twice daily for three months. Sixty-six patients completed the study, and overall positive outcomes were observed in 47% of women, with 61% in the treatment group and 38% in the placebo group, although the results did not reach statistical significance ($P = 0.069$). In women with amenorrhea or luteal-phase dysfunction, pregnancy resulted twice as often in the treatment group (15%) versus the placebo group (7%); however, no statistical analysis was reported (30).

In open (uncontrolled) trials involving 48 (45 completed) infertile women (due to luteal-phase dysfunction), the efficacy of a VAC fruit extract for the normalization of progesterone concentrations was determined (47). Inclusion criteria were normal prolactin levels (below 20 ng/mL), normal results in prolactin and thyroid stimulating stimulation (TSH) tests, and an abnormally low serum progesterone level below 12 ng/mL on the 20th day of the cycle. Treatment consisted of a fruit extract, 40 drops daily, without any other medication for three months. Forty-five patients completed the studies (three were excluded because of concurrent hormone use). The outcome of therapy was assessed by the normalization of the mid-luteal progesterone concentration and correction (lengthening) of any preexisting shortening of the phases of the cycle. Treatment was successful in 39 out of the 45 women. Seven subjects became pregnant. In 25 patients, serum progesterone was restored to normal (> 12 ng/mL), and in seven cases, there was a trend toward normalization of progesterone levels. However, no statistical analysis was performed on the resultant data (47).

Two larger postmarketing trials, involving 479 women, assessed the safety and efficacy of a VAC fruit extract for the treatment of oligomenorrhea or polymenorrhea (48). The subjects were treated with 30 drops of the extract twice daily and the outcome measured was the bleeding-free interval. A lengthening of the bleeding-free interval was observed for 35 days in 187/287 women receiving treatment for oligomenorrhea and 26 days in 139/192 patients being treated for polymenorrhea (48).

MENOPAUSAL SYMPTOMS

The efficacy of a combination product containing *Hypericum perforatum* (St. John's wort) and VAC (300 mg and 500 mg, respectively) for the management of menopausal

symptoms was investigated in a double-blind, randomized, placebo-controlled, parallel study (49). The trial was performed over 16-week period and involved 100 eligible late-perimenopausal or postmenopausal women experiencing hot flushes and other menopausal symptoms. The herbal combination therapy or placebo tablets were administered twice daily. The primary endpoint was a reduction in hot flush episodes. Secondary endpoints included Greene Climacteric Scale scores, Hamilton Depression Inventory scores, and Utian Quality of Life Scale scores. Of the 100 women that started the trial, 93 women completed the study. Data analysis on an intent-to-treat basis found no significant differences between the two groups for any of the endpoints. Analyses performed at interim data time points revealed no significant differences at week 4, 8, or 12 for daily weighted flushes or scores on the Greene Climacteric Scale scores or Hamilton Depression Inventory scores. No significant change was found for either group on quality of life. The herbal combination was well tolerated with no significant adverse events noted in the short term (49).

Endocrine-Dependent Dermatoses

Two uncontrolled clinical studies and one observational report have assessed the effects of a VAC fruit extract on acne caused by a hormone imbalance (6–8). In one open study, 118 cases of acne were treated with a VAC extract (20 drops twice daily for 4–6 weeks, and then 15 drops twice daily for 1–2 years) and compared with conventional acne treatments (8). Patients treated with the fruit extract reported a more rapid healing rate after six weeks and after three months of therapy, whereas 70% of subjects taking the VAC extract stated complete healing.

ADVERSE EFFECTS

In general, VAC products and extracts appear to be very well tolerated and there have been few accounts of adverse reactions (ARs). A review of 30 human studies, involving 11,506 subjects, reported a total of 246 adverse events, thus representing an AR rate of approximately 2% (2). The major ARs included acne, cycle changes, dizziness, gastrointestinal distress, increased menstrual flow, nausea, skin reactions, urticaria, and weight gain (2). Minor side effects include fatigue, hair loss, increased intraocular pressure, palpitations, polyurea, sweating, and vaginitis (2,46). One case of multiple follicular development was reported in a female patient after self-medication with a VAC-containing product for infertility (50).

Although the potential estrogenic effects of VAC extracts are weak (51,52), its use during pregnancy or in women with estrogen-dependent breast cancer should not be recommended. In addition, patients with a feeling of tension and swelling of the breasts or other menstrual disturbances should consult a healthcare provider for medical diagnosis (28). Although there are no drug interactions reported, the potential dopaminergic effects of VAC extracts may reduce the efficacy of dopamine-receptor antagonists (23,53). Furthermore, because of possible hormonal effects, VAC may interfere with the effectiveness of oral contraceptives and hormone therapy (2).

MECHANISM OF ACTION

Several potential mechanisms of action have been proposed to explain the activity of VAC extracts, including inhibition of prolactin secretion (50–51) and dopaminergic (53,54) and estrogenic effects (51,55–57). Extracts have been shown to act as a dopamine agonist in vitro and in vivo. The binding of an ethanol VAC extract and various fractions of the extract to the dopamine D₂ and other receptors were evaluated by both radioligand binding studies and by superfusion experiments (54). The extract bound to the dopamine D₂ and opioid (μ and κ subtype) receptors with a median inhibitory concentration ranges between 20 and 70 $\mu\text{g/mL}$. Binding was not observed for the histamine H₁, benzodiazepine and OFQ receptors, or the serotonin transporter. Two diterpenes, isolated from a hexane fraction of the extract, rotundifuran and 6 β ,7 β -diacetoxy-13-hydroxy-labda-8,14-diene (Fig. 2), exhibited inhibitory actions on dopamine D₂ receptor binding with a median inhibitory concentration of 45 and 79 $\mu\text{g/mL}$, respectively (26,54). While lipophilic fractions of the extract bound to the μ - and κ -opioid receptors, binding to delta opioid receptors was inhibited primarily by an aqueous fraction of the extract. In superfusion experiments, the aqueous fraction of a methanol extract inhibited the release of acetylcholine in a concentration-dependent manner. In addition, the D₂ receptor antagonist spiperone antagonized the effect of the extract suggesting a dopaminergic action mediated by D₂ receptor activation. A labdane diterpene, α -acetoxy-13-hydroxylabdadiene (Fig. 2), isolated from a fruit extract, was found to displace ¹²⁵I-sulpiride from recombinant human D₂ receptor binding sites in a dose-dependent manner (58). This group also demonstrated that rotundifuran, at a concentration of 100 μM , significantly ($P < 0.05$) inhibited the secretion of prolactin from cultured rat pituitary cells.

Several groups have demonstrated that extracts bind to the estrogen receptor and have weak estrogenic effects, suggesting that chasteberry may also affect the estrogen/progesterone balance (51,56–58). A methanol extract of the fruit bound to both ER α and ER β induced the expression of estrogen-dependent genes, progesterone receptor (PR), and presenilin-2 (pS2) in Ishikawa cells (51). Significant binding affinity for both ER α and ER β was observed, with a median inhibitory concentration of 46.3 and 64.0 $\mu\text{g/mL}$, respectively. However, the binding affinity of the extract for ER α and ER β was not significantly

Figure 2 2- α -Acetoxy-13-hydroxylabdadiene, rotundifuran, and 6 β ,7 β -diacetoxy-13-hydroxy-labda-8,14-diene.

different (51). Based on bioassay-guided isolation, the "estrogenic" component from the fruit extract was identified as linoleic acid (LA), which also bound to ER α and ER β (52). Similar to the extract, LA also induced the expression of the PR mRNA in Ishikawa cells, at a concentration of 1 μ g/mL, indicating that binding produced a biological estrogenic effect in vitro. In addition, low concentrations of the extract or LA (10 μ g/mL) upregulate the expression of ER β mRNA in the ER plus hormone-dependent T47D:A18 cell line, a further indication of estrogenic activity (52). Recently, it has been suggested that methanol extracts of VAC may also activate the μ -opiate receptor, thereby exerting its effects on endogenous opiate peptides such as β -endorphin (50). This peptide assists in regulating the menstrual cycle through the inhibition of the hypothalamus-pituitary-adrenal axis through a complex feedback loop involving estrogen and progesterone (50). Levels of β -endorphin decrease along with estrogen in the late-luteal phase of the menstrual cycle, which correlated with the development of PMS symptoms (50). Thus, since VAC activates the μ -opiate receptor, it may increase the levels of β -endorphin, thereby having beneficial effects on PMS.

SAFETY

A recent review of the safety of VAC administration during pregnancy and lactation used database searches of published literature and case reports (59). The review concluded that in pregnancy, there is little evidence supporting the use of VAC during pregnancy based on theoretical and expert opinion and in vitro studies that chaste tree may have estrogenic and progestogenic activity, uterine stimulant activity, emmenagogue activity, and prevent miscarriages. In lactation, the data are conflicted as to whether chaste tree increases or decreases lactation. Thus, recommendations of VAC use during pregnancy and lactation are currently unsubstantiated and require further investigations for both safety and efficacy.

Choline

Steven H. Zeisel

INTRODUCTION

Name and General Description

Choline, an essential nutrient for humans, is consumed in many foods. It is a constituent of all cell membranes and is necessary for growth and development. Also, as the major precursor of betaine, it is used by the kidney to maintain water balance and by the liver as a source of methyl groups for the removal of homocysteine in methionine formation. Finally, choline is used to produce the important neurotransmitter (nerve messenger chemical) acetylcholine, which is involved in memory and other nervous system functions (Fig. 1). Maternal diets deficient in choline during the second half of pregnancy in rodents caused decreased neurogenesis and increased neuronal apoptosis in fetal hippocampus (the memory center), resulting in permanent behavioral (memory) modifications in the offspring. Dietary deficiency of choline in rodents causes development of liver cancer in the absence of any known carcinogen. In humans, dietary deficiency of choline is associated with fatty liver and liver damage. The dietary requirement for choline is influenced

by gender as well as by genetic polymorphisms. Using a comprehensive database of the choline content of foods, a number of epidemiological studies identified associations between dietary choline intake and plasma homocysteine levels (risk factor for cardiovascular disease), cancer, and birth defects.

BIOCHEMISTRY AND RELATIONSHIPS WITH OTHER NUTRIENTS

Choline is needed for synthesis of several major phospholipids (phosphatidylcholine and sphingomyelin) in cell membranes and is also involved in methyl metabolism, cholinergic neurotransmission, transmembrane signaling, and lipid-cholesterol transport and metabolism (1) (Fig. 2). Choline can be acetylated, phosphorylated, oxidized, or hydrolyzed. There are several comprehensive reviews of the metabolism and functions of choline (1).

Cells absolutely require choline and die by apoptosis when deprived of this nutrient (2,3). Humans derive choline from foods, as well as from the *de novo* biosynthesis of the choline moiety via the methylation of phosphatidylethanolamine using (*S*)-adenosylmethionine as the methyl donor (most active in the liver). This ability to form choline means that some of the demand for choline can, in part, be met by using methyl groups derived from one carbon metabolism (via methyl-folate and methionine). Several vitamins (folate, vitamin B₁₂, vitamin B₆, and riboflavin) and the amino acid methionine interact with choline in 1-carbon metabolism. There has been renewed interest in these pathways during the past several years, engendered by recent insights that indicate that modest dietary inadequacies of the above-mentioned nutrients, of a degree insufficient to cause classical deficiency syndromes, can still contribute to important diseases such as neural tube defects, cardiovascular disease, and cancer (4).

Perturbing the metabolism of one of these pathways results in compensatory changes in the others (1). For example, methionine can be formed from homocysteine using methyl groups from methyl-tetrahydrofolate (THF), or using methyl groups from betaine that are derived from choline. Similarly, methyl-THF can be formed from one-carbon units derived from serine or from the methyl groups of choline via dimethylglycine, and choline can be synthesized *de novo* using methyl groups derived from methionine [via (*S*)-adenosylmethionine]. When animals and humans are deprived of choline, they

Phosphatidylcholine

Figure 1 Chemical structures of choline and related compounds.

Figure 2 Pathways of choline metabolism

Choline can be a methyl-group donor and interacts with methionine and folate metabolism. It can be acetylated to form the neurotransmitter acetylcholine, and it can be phosphorylated to form membrane phospholipids such as phosphatidylcholine (lecithin) and sphingomyelin. Choline can be formed via the methylation of phosphatidylethanolamine (forming phosphatidylcholine, which can be hydrolyzed to make choline).

There is no estimate for percentage absorption of the various forms of choline in humans. The water-soluble choline-derived compounds (choline, phosphocholine, and glycerophosphocholine) are absorbed via the portal circulation, whereas the lipid-soluble compounds (phosphatidylcholine and sphingomyelin) are absorbed as chylomicrons. Lecithin is the most abundant choline-containing compound in the diet. About half of the lecithin ingested enters the thoracic duct, and the remaining is metabolized to glycerophosphocholine in the intestinal mucosa and then to choline in the liver. The liver takes up the majority of choline and stores it in the form of phosphatidylcholine and sphingomyelin. The kidney and the brain also accumulate choline. Although some free choline is excreted with urine, most is oxidized in the kidney to form betaine, which is responsible for maintaining the osmolarity in the kidney. A specific carrier is needed for the transport of free choline across the blood-brain barrier; the capacity is especially high in neonates.

Choline and other methyl donors are important dietary modulators of epigenetic marks on genes. The term “epi-

Examples of epigenetic effects of choline and other methyl donors include experiments in rodents in which pregnant dams were fed diets that were choline deficient versus normal, and DNA methylation in fetal brain was modified, resulting in over expression of genes that inhibit cell cycling in neural progenitor cells of developing brain (12,13). Gestational choline availability also affects histone methylation in the developing embryo, resulting in changes in expression of genes that regulate methylation and neuronal cell differentiation (14). Feeding pregnant Pseudoagouti *Avy/a* mouse dams a choline and methyl-supplemented diet altered epigenetic regulation of agouti expression in their offspring, as indicated by increased agouti/black mottling of their coats and by lean body phenotype (15,16). In another example, choline and methyl donor supplementation to dams increased DNA methylation of the fetal gene *Axin fused* [*Axin(Fu)*] and reduced incidence of tail kinking in *Axin(Fu)*/+ offspring by 50% (17). Thus, dietary manipulation of choline and methyl donors (either deficiency or supplementation) can have a profound impact upon gene expression.

HUMAN REQUIREMENT FOR CHOLINE

In one of the first clinical nutrigenomics studies, humans were phenotyped with respect to their susceptibility to developing organ dysfunction when fed a low-choline diet (18–21). Adult men and women (pre- and postmenopausal) aged 18 to 70 years were fed a standard diet containing a known amount of choline (550 mg/70 kg/day; baseline) for 10 days. On day 11 subjects were placed on a diet containing less than 50 mg choline/day for up to 42 days. Blood and urine were collected to measure various experimental parameters of dietary choline status, and markers of organ dysfunction and liver fat were assessed. If at some point during the depletion period, functional markers indicated organ dysfunction associated with choline deficiency, subjects were switched to a diet containing choline until replete.

Most men and postmenopausal women fed the low-choline diets developed reversible fatty liver (measure by mass resonance spectroscopy) as well as liver and muscle damage, whereas 56% of premenopausal women were resistant to developing choline deficiency (21). The fatty liver occurred due to lack of phosphatidylcholine synthesis in liver, which is required for very low density lipoprotein (VLDL) synthesis needed for export of excess triacylglycerol from liver (22). Choline deficiency liver damage was characterized by elevated serum aminotransferase (23) and muscle damage was characterized by elevated plasma serum creatine phosphokinase (19): both were due to increased rates of apoptosis in these tissues (also occurred in peripheral lymphocytes (24)). Choline-deficient subjects also had impaired ability to handle a methionine load, resulting in elevated plasma homocysteine concentrations (20,25).

Only 44% of premenopausal women develop signs of choline deficiency when deprived of dietary choline as compared with most adult men and postmenopausal women, suggesting their higher resistance to choline deficiency (19,20). Premenopausal women required less dietary choline because estrogen induces the phosphatidylethanolamine-*N*-methyltransferase (PEMT) gene to enhance the *de novo* biosynthesis of choline moiety (26). Estrogen binds to its receptors, and this complex interacts with estrogen response elements (EREs) in the promoter of the PEMT gene, resulting in an upregulation in PEMT mRNA expression and in hepatic upenzyme activity (26). Estrogen as the mediator of increasing PEMT activity in women is important, especially during pregnancy when fetal development uses a great deal of choline. Estradiol concentration rises from 1 to 60 nM during pregnancy (27,28), suggesting that the capacity for endogenous synthesis of choline should be highest when choline is needed most. Pregnancy and lactation are stages of life that demand high dietary choline intake and leave mothers extremely vulnerable to choline deficiency (29). In utero, the fetus is exposed to very high choline concentrations, with a progressive decline in blood choline concentration until adult levels of choline concentration are achieved after the first weeks of life (30). Plasma or serum choline concentrations are 6–7× higher in the fetus and newborn than those in adults (31,32). High circulating choline in the fetus and neonate ensures the availability of choline to tissues.

Less than 15% of pregnant women consume the recommended adequate intake for choline (33), and in case-control studies in California, women eating diets in the lowest quartile for choline were at fourfold increased risk for having a baby with a neural tube defect and at almost twofold increased risk for having a baby with a cleft palate; these risks were calculated after controlling for folate intake (34,35).

Genetics of Choline Requirements

Although premenopausal women are more resistant to choline deficiency, a significant portion of them (44%) still develops organ dysfunction when deprived of choline, suggesting individual differences in susceptibility to choline deficiency. In fact, some men and women require more than 850 mg/70 kg/day choline in their diet, whereas others require less than 550 mg/kg/day (21). Genetic variation likely underlies the differences in these dietary requirements. A single-nucleotide polymorphism (SNP) is a genetic variation occurring when a single nucleotide (A, T, C, or G) in the genome sequence is altered. These variations may affect metabolism. Only a few reports investigate whether SNPs in the genes involved in one carbon metabolism have roles in choline requirements (36,37). Premenopausal women with a SNP in 5,10-methylenetetrahydrofolate dehydrogenase (MTHFD1 rs2236225) were 15× more susceptible to choline deficiency than did noncarriers. This variant increased the use of choline perhaps by limiting the availability of methyl-folate for Hcy remethylation and increasing the demand for choline as a methyl-group donor. In addition, individuals with a SNP in PEMT (rs12325817) were more susceptible to choline deficiency, and women harboring this SNP were more affected than did men. SNPs in the PEMT gene alter endogenous synthesis of choline, thereby increasing the dietary requirement for choline.

Dietary Recommendations

In 1998, the Institute of Medicine (IOM) made recommendations for choline intake in the diet (4). At the time, there were insufficient data with which to derive an estimated average requirement for choline, thus only an adequate intake (AI) could be estimated. The IOM report cautioned, “this amount will be influenced by the availability of methionine and methyl-folate in the diet. It may be influenced by gender, and it may be influenced by pregnancy, lactation, and stage of development. Although AIs are set for choline, it may be that the choline requirement can be met by endogenous synthesis at some of these stages.” The IOM recommendations are summarized in Table 1.

Food Sources

In foods, there are multiple choline compounds that contribute to total choline content (choline, glycerophosphocholine, phosphocholine, phosphatidylcholine, and sphingomyelin) (7). The U.S. Department of Agriculture (USDA) maintains a database of choline content in foods (38). Excellent sources of dietary choline are foods that contain membranes, such as eggs and liver. Average dietary choline intake on *ad libitum* diets for males and females are 8.4 and 6.7 mg/kg choline per day, respectively (39). Foods also contain the choline metabolite

Table 1 Recommended Adequate Intakes (AIs) of Choline for Humans

AI for infants	0–6 mo	125 mg/day, 18 mg/kg
	6–12 mo	150 mg/day
AI for children	1–3 yr	200 mg/day
	4–8 yr	250 mg/day
	9–13 yr	375 mg/day
AI for males	14–18 yr	550 mg/day
	19 yr and older	550 mg/day
AI for females	14–18 yr	400 mg/day
	19 yr and older	425 mg/day
AI for pregnancy	All ages	450 mg/day
AI for lactation	All ages	550 mg/day

Source: From Ref. 4.

betaine, which spare choline requirements (40). Human milk is rich in choline. Choline is routinely added to commercially available infant formulas. Until recently some infant formulas had inadequate choline content (especially soy-derived infant formulas), but in 2007–2008, many infant formula companies increased the choline content of their formulas so that they matched mature breast milk. These formulas still have different mixtures of the esters of choline than are present in human milk, perhaps resulting in different bioavailability as compared to human milk (41).

Adverse Effects

High doses of choline (>6 g) have been associated with excessive cholinergic stimulation, such as vomiting, salivation, sweating, and gastrointestinal effects (4). In addition, fishy body odor results from the excretion of trimethylamine, a choline metabolite from bacterial action (24). The tolerable upper limit for choline has been set at 3 g/day (4).

Assessing Choline Status

Measurement of choline and choline metabolites is useful in estimating choline status, but the measure is not definitive. Plasma choline concentration varies in response to diet and can rise as much as twofold after a two-egg meal. Fasting plasma choline concentrations vary from 7 to 15 μ M, with most subjects having concentrations of 10 μ M. Individuals that have starved for up to seven days have diminished plasma choline, but levels never drop below 50% of normal, probably because tissue phospholipids are “cannibalized” to prevent concentrations of choline from falling further (42). Note that children during the first year of life have normal plasma choline concentrations that are higher than 10 to 15 μ M (43). Plasma phosphatidylcholine concentration also decreases in choline deficiency (44), but these values are also influenced by factors that change plasma lipoprotein levels. Fasting plasma phosphatidylcholine concentrations are approximately 1 to 1.5 mM. Thus, measurements of choline or phosphatidylcholine in blood identify subjects with low dietary choline intake, but provide little help in differentiating the degree of deficiency.

CHOLINE AND CARDIOVASCULAR DISEASE

Choline and betaine may benefit heart health by lowering blood pressure, altering blood lipid profiling, and reducing plasma Hcy, a risk factor for cardiovascular disease

(CVD) (45). Dietary choline intake was found to have a statistically significant inverse relationship to circulating Hcy concentrations in the Framingham Heart Study (46) and in the Nurse’s Health Study (25), suggesting a protective effect of choline intake. However, when looking at the association between dietary choline intake and CVD incidence, no association was found (14) in the European Prospective Investigation into Cancer and Nutrition (EPIC) study (47), and a marginal positive association was found in the Atherosclerosis Risk in Communities (ARIC) study (48). It is important to note that in the ARIC study, most individuals in the cohort had choline intake below AI (49). Hence, the effects of choline supplementation on CVD risk remain unknown. Some human studies suggested that high betaine supplementation increases plasma low-density lipoprotein (LDL) cholesterol and triacylglycerol concentrations (50–52), effects that might counterbalance its Hcy lowering effects. However, the changes in serum lipid concentrations were not associated with higher risk of CVD. Moreover, the rise in LDL concentration may be an artifact of increasing VLDL and triacylglycerol excretion from fatty liver to plasma, which is not an adverse outcome (for critical review see Ref. 53). The relationship between choline and heart health warrants more study.

The choline-containing phospholipid phosphatidylcholine has been used as a treatment to lower the cholesterol concentrations because lecithin-cholesterol acyltransferase has an important role in the removal of cholesterol from tissue. Betaine, the oxidized product of choline, has been used to normalize the plasma homocysteine and methionine levels in patients with homocystinuria, a genetic disease caused by 5,10-methylenetetrahydrofolate reductase deficiency. Therefore, dietary choline intake might be correlated with cardiovascular disease risk. Many epidemiologic studies have examined the relationship between dietary folic acid and cancer or heart disease. It may be helpful to also consider choline intake as a confounding factor because folate and choline methyl donation can be interchangeable (7).

CHOLINE DEFICIENCY AND CANCER

An interesting effect of dietary choline deficiency in rats and mice has never been studied in humans. Dietary deficiency of choline in rodents causes development of hepatocarcinomas in the absence of any known carcinogen (54). Choline is the only single nutrient for which this is true. It is interesting that choline-deficient rats not only have a higher incidence of spontaneous hepatocarcinoma but also are markedly sensitized to the effects of administered carcinogens. Several mechanisms are suggested for the cancer-promoting effect of a choline-free diet. These include increased cell proliferation related to regeneration after parenchymal cell death occurs in the choline-deficient liver; hypomethylation of DNA (alters expression of genes); reactive oxygen species leakage from mitochondria with increased lipid peroxidation in liver; activation of protein kinase C signaling due to accumulation of diacylglycerol in liver; mutation of the fragile histidine triad (FHIT) gene, which is a tumor suppressor gene; and defective cell-suicide (apoptosis) mechanisms

(54). Loss of PEMT function may also contribute to malignant transformation of hepatocytes (55).

Only a handful of epidemiologic studies explore how choline and betaine intakes alter cancer risk in populations. This was perhaps due to the absence of food composition data, which has not been developed until recently (7). The Long Island Breast Cancer Study found that high choline consumption was associated with reduced breast cancer risk (56), and high choline and betaine consumption was associated with reduced breast cancer mortality (57). Moreover, individuals with *PEMT* rs12325817 and *CHDH* rs12676 SNPs had lower risk of developing breast cancer, whereas *BHMT* rs3733890 had lower breast cancer mortality. These data suggest the importance of nutrients and genetic interactions in the etiology of cancer. Alternatively, the Nurse's Health Study II found no association between choline intake and breast cancer risk (58), but a positive association between choline intake and colorectal cancer risk (59), suggesting different etiologies between breast and colorectal cancer. More research is warranted.

CHOLINE AND BRAIN

Choline and Brain Development

In rodents, maternal dietary choline intake during late pregnancy modulated mitosis and apoptosis in progenitor (stem) cells of the fetal hippocampus and septum and altered the differentiation of neurons in fetal hippocampus (60). Variations in maternal dietary choline intake (choline supplementation or choline deficiency) during late pregnancy were also associated with significant and irreversible changes in hippocampal function in the adult animal, including altered long-term potentiation (LTP) and altered memory (61). More choline (about 4× dietary levels) during days 11–17 of gestation in the rodent increased hippocampal progenitor cell proliferation, decreased apoptosis in these cells, enhanced LTP in the offspring when they were adult animals, and enhanced visuospatial and auditory memory by as much as 30% in the adult animals throughout their lifetimes (61). The enhanced maze performance appears to be due to choline-induced improvements in memory capacity. Indeed, adult rodents decrement in memory as they age, and offspring exposed to extra choline in utero do not show this “senility” (62). In contrast, mothers fed choline-deficient diets during late pregnancy have offspring with diminished progenitor cell proliferation and increased apoptosis in fetal hippocampus, insensitivity to LTP when they were adult animals, and decremented visuospatial and auditory memory (61).

Early postnatal choline supplementation significantly attenuated the effects of prenatal alcohol on a learning task, suggesting that early dietary interventions may also influence brain development (63). The mechanisms for these developmental effects of choline are not yet clear. Fetal alcohol syndrome (FAS) is an important concern of pediatricians, with 1 in every 750 infants born with FAS each year in the United States. Rats exposed to alcohol during the perinatal period had poor performance on memory tasks, which were improved by either prenatal or postnatal choline supplementation (64,65). Rett syndrome (RTT), a neurodevelopmental disorder associated with mutations

in the methyl-CpG-binding protein 2 (MeCP2) gene, is the second leading cause of mental retardation in girls. RTT girls experience a variety of deficits in cognitive, motor, and social functions. In mouse models of RTT, enhancing maternal or postnatal choline supplementation attenuates motor coordination deficits and improves neuronal integrity, proliferation, and survival (66,67). Choline supplementation also ameliorates the symptoms in rodent models of traumatic brain injury (68), status epilepticus (69–71), and schizophrenia (72).

Are these findings in animals likely to be true in humans? We do not know. Human and rat brains share many elements of brain development but they mature at different rates. In terms of hippocampal development, the embryonic days 12–18 in the rat correspond to approximately the last trimester in humans. Rat brain is comparatively more mature at birth than is the human brain, but human hippocampal development may continue for months or years after birth.

Choline and Adult Brain

Acetylcholine is one of the most important neurotransmitters used by neurons in the memory centers of brain (hippocampus and septum). Choline accelerates the synthesis and release of acetylcholine in nerve cells. Choline used by brain neurons is largely derived from membrane lecithin, or from dietary intake of choline and lecithin. Free choline is transported across the blood–brain barrier at a rate that is proportional to serum choline level; lecithin may be carried into neurons as part of an ApoE lipoprotein. Choline derived from lecithin may be especially important when extracellular choline is in short supply, as might be expected to occur in advanced age because of decreased brain choline uptake (73).

Results from studies using choline or phosphatidylcholine to treat adults with brain disorders have been very variable. Single doses of choline or lecithin in adult humans may enhance memory performance in healthy individuals, perhaps with greatest effect in individuals with the poorest memory performance. Studies in students showed that lecithin or choline treatment improved memory transiently for hours after administration (74). In humans with Alzheimer-type dementia, some studies report enhanced memory performance after treatment with lecithin (75), whereas other studies did not observe this. Buchman et al. recently reported that humans on long-term total parenteral nutrition may have verbal and visual memory impairment, which may be improved with choline supplementation (76). If lecithin is effective, it is in a special subpopulation in the early stages of the disease. Choline and lecithin have also been effectively used to treat tardive dyskinesia, presumably working by increasing cholinergic neurotransmission (77).

CONCLUSION

Choline in the diet is important for many reasons. Humans deprived of it develop liver and muscle dysfunction, and parenterally nourished patients need a source of choline. As our understanding of the importance of folate and homocysteine nutrition increases, there should be increased interest in how choline interacts with these compounds.

Recent findings about choline in brain development in animals should stimulate comparable studies in humans. The availability of food composition data now makes it possible to examine interactions between choline, folate, and methionine when considering epidemiological data.

Chondroitin Sulfate

Karla L. Miller and Daniel O. Clegg

INTRODUCTION

Osteoarthritis (OA) is the most common arthropathy worldwide and a significant cause of morbidity and disability, especially in the elderly (1). Both biomechanical forces and biochemical processes are important in its pathogenesis, which is characterized by progressive deterioration of articular cartilage causing debilitating pain and loss of normal joint motion. Standard therapies can alleviate the symptoms of OA to some extent but have no ability to prevent disease progression. A number of alternative substances, collectively referred to as nutraceuticals, have been touted in the lay press as being beneficial for OA, with particular interest focused on glucosamine and chondroitin sulfate (2,3).

Chondroitin sulfate is a key component of normal cartilage that is substantially reduced in the cartilage of individuals with OA. This observation stimulated interest in its potential role as a therapeutic agent, and continuing investigations have now identified a number of apparent biologic actions. No consensus exists, however, as to its clinical efficacy or utility. While it has gained a measure of acceptance in Europe, physicians in the United States appear to be less convinced by the available clinical data. Nonetheless, the interest of the general population has been piqued, and owing to its universal availability as an over-the-counter supplement, present use of chondroitin sulfate, either with or without standard OA therapy, is not uncommon (4).

STRUCTURE, BIOCHEMISTRY, AND PHYSIOLOGY

Chondroitin sulfate is classified as a glycosaminoglycan (GAG) and is present abundantly in articular cartilage as well as in many other tissues, including bone, tendon, intervertebral disk, aorta, cornea, and skin. It is composed of alternating *N*-acetylgalactosamine and *D*-glucuronic acid residues, which form a long, unbranched chain. While the length of the chain is variable, it seldom exceeds 200 to 250 disaccharide units. Sulfation occurs at the 4 or 6 position of the *N*-acetylgalactosamine residue to produce chondroitin 4-sulfate (chondroitin sulfate A) and chondroitin 6-sulfate (chondroitin sulfate C), respectively, whereas the substitution of *L*-iduronic acid for *D*-glucuronic acid produces dermatan sulfate, formerly known as chondroitin sulfate B (Fig. 1).

The significance of the sulfation position is not fully understood but appears to be associated with tissue age and location. Sulfation at the 4 position is seen more frequently in deeper, immature cartilage, while older, thinner cartilage is primarily sulfated at the 6 position (5). Addi-

tionally, abnormalities in sulfation appear to be present in OA cartilage (6), although their physiologic significance is uncertain.

The chondroitin sulfates comprise one of three primary divisions of GAGs, heparins and keratan sulfates being the other two. GAGs are synthesized intracellularly by chondrocytes, synoviocytes, fibroblasts, and osteoblasts. Following synthesis, multiple GAGs attach to a protein core within the Golgi apparatus to form a proteoglycan, which is subsequently secreted into the extracellular matrix (7). The factors that promote and regulate proteoglycan biosynthesis are complex, and it has been estimated that more than 10,000 enzymatic steps may be required (8).

The predominant proteoglycan in human articular cartilage is aggrecan, which contains both chondroitin sulfate and keratan sulfate side chains. Together, these side chains account for 80% to 90% of the mass of aggrecan. Chondroitin sulfate predominates over keratan sulfate, with more than 100 chondroitin sulfate side chains being present on a single aggrecan molecule. While there is some variability in the core protein, the physical and chemical properties of proteoglycans are largely attributable to the chondroitin sulfate side chains. One important feature of the proteoglycans is a marked negative electrical charge, which is created by the ionized sulfate groups within the GAG side chains.

Chondroitin sulfate A

Chondroitin sulfate C

Figure 1 Structure of chondroitin 4-sulfate (chondroitin sulfate A) and chondroitin 6-sulfate (chondroitin sulfate C).

Articular cartilage consists of collagen fibers surrounded by a matrix containing aggregates of aggrecan and hyaluronate. Within the matrix, 100 to 200 aggrecan molecules bind to a single hyaluronate strand to form a supramolecular structure large enough to be seen by electron microscopy. The tensile strength of articular cartilage is the result of a network of collagen fibers, while the aggrecan-hyaluronate aggregates, which are rich in chondroitin sulfate chains, provide resiliency. Under normal circumstances, water is electrically attracted to cartilage by the negatively charged GAG residues and becomes entrapped within the aggregates. When a deforming force (such as occurs with weight bearing) is applied to the cartilage surface, minimal deformity occurs under normal conditions because the movement of water within cartilage is resisted by (i) its electrical affinity to the GAG residues, and (ii) the physical obstruction created by the bulky aggrecan-hyaluronate aggregates.

In OA, deterioration of articular cartilage is associated with a loss of proteoglycan, with a consequent change in water content and decrease in resilience. The pathogenetic events producing these changes remain uncertain but may result from changes in proteoglycan catabolism involving matrix metalloproteases, serine proteases, glycosidases, and chondroitinases secreted from chondrocytes and other connective tissue cells (9). Experimental models of OA suggest that synthesis of aggrecan increases early in the degenerative process in an apparent attempt at cartilage repair. The chondroitin sulfate side chains synthesized in this setting, however, are longer and more antigenic, suggesting that important GAG constitutional and/or conformational changes may be involved in the pathogenesis of OA (9). One such change appears to involve the terminal sulfation of chondroitin (10). Further study of the mechanisms that produce changes in the GAG synthesis may yet yield a site for therapeutic intervention that might have disease-modifying potential.

PHARMACOLOGY

The pharmacologic properties of exogenously administered chondroitin sulfate have been examined in a number of animal models and in humans with doses ranging from 60 mg/kg to 2 g/kg. Various routes of administration have been utilized in these studies, including oral, intraperitoneal, subcutaneous, and intravenous (11). In general, chondroitin sulfate appears to be well tolerated, and no significant adverse events have been reported with any route of administration. Determinations of oral bioavailability have yielded estimates of 5% to 15%, with blood levels reported to peak between 2 and 28 hours (12,13) following administration. No significant difference was observed between divided and single day dosing, while sustained dosing yielded serum levels only slightly higher than those seen following a single dose (12). The elimination half-life has been estimated at six hours. With a radiolabeled preparation of chondroitin sulfate administered orally to rats, more than 70% of the radioactivity was absorbed and subsequently identified in either the tissues or the urine. Radioactivity was found in every tissue examined at 24 hours, with levels variably diminished at 48 hours except in joint cartilage, the eye, the brain, and

adipose tissue, where levels were increased (12). There are very limited data for chondroitin sulfate pharmacokinetics when it is administered in conjunction with glucosamine.

The variability in pharmacokinetic derivations reported to date is considerable and appears to be principally due to methodological differences and limitations. Early studies that utilized radioactive forms of chondroitin sulfate (tritiated) in animals were complicated by the production of tritiated water, which introduced error into concentration determinations, while assays utilizing high-performance liquid chromatography (HPLC) methodology were unable to detect low concentrations of chondroitin sulfate. More recent work in humans is similarly problematic due to assay insensitivity, failure to account for endogenous chondroitin sulfate levels, and/or the use of diluents for anticoagulation. Newer technologies now permit the reliable quantitation of GAG at lower levels (14), and a pharmacokinetic study incorporating these techniques is being contemplated in conjunction with the Glucosamine/Chondroitin Arthritis Intervention Trial (GAIT).

CHONDROITIN SULFATE PREPARATIONS

Chondroitin sulfate is produced by several manufacturers and is readily available worldwide. It is derived by extraction from bovine, porcine, or shark cartilage. Various methods of extraction exist, but the specifics of each process are the proprietary information of the manufacturer. Most processes start with some form of enzymatic digestion followed by a variable number of washings, incubations, and elutions. In contrast to the procedure with prescription medications, the production process is not strictly regulated, and variations in quality and potency can occur from batch to batch and from manufacturer to manufacturer.

In a study conducted to identify a high-quality chondroitin sulfate dosage form for use in a clinical trial, three different sources of purified chondroitin sulfate were evaluated in a blinded fashion. While each sample exhibited similar disaccharide and GAG content overall, chondroitin sulfate potency varied by 15% to 20% (15).

In the United States, chondroitin sulfate is classified as a nutritional supplement and is widely available without a prescription in pharmacies and health and natural food stores. Not infrequently, it is manufactured in combination with glucosamine.

PUTATIVE MECHANISMS OF ACTION

A number of possible mechanisms of action for chondroitin sulfate in the treatment of OA have been suggested from pilot studies in animals and humans. Additional investigations are needed to confirm and extend these preliminary observations.

- a. *Inhibition of matrix proteases and elastases.* Articular cartilage is catabolized by proteinases and elastases that are elaborated from chondrocytes and leukocytes,

respectively. In both in vitro and in vivo studies with rodents, a modest decrease in elastase activity was seen following chondroitin sulfate administration. A similar chondroitin sulfate effect on neutral proteases has also been observed. The mechanism of this apparent inhibitory effect of chondroitin sulfate may be ionic disruption at the catalytic site of the enzyme. Chondroitin 6-sulfate may be more potent than chondroitin 4-sulfate (16).

- b. *Stimulation of proteoglycan production.* Several studies have shown that proteoglycan synthesis in vitro increases when chondroitin sulfate is added to cultures of chondrocytes and synoviocytes (17–19). The mechanism by which this occurs is unknown, but increased RNA synthesis has been observed, as well as TNF- α inhibition and IL-1 β antagonism.
- c. *Viscosupplementation.* An increase in synovial fluid viscosity has been reported following the administration of oral chondroitin sulfate to rabbits, rats, and horses (17,20,21). A more viscous synovial fluid may interfere physically with cartilage matrix catabolism, but the mechanism by which chondroitin sulfate might increase the viscosity of synovial fluid is uncertain.
- d. *Anti-inflammatory action.* Chondroitin sulfate has been reported to decrease leukocyte chemotaxis, phagocytosis, and lysosomal enzyme release in vitro. When administered orally to rodents, it appeared to decrease granuloma formation in response to sponge implants as well as attenuate the inflammatory response in adjuvant arthritis and carrageenan-induced pleurisy (22).

CLINICAL STUDIES

Interest in chondroitin sulfate as a therapeutic agent is longstanding and has primarily focused on the treatment of OA. Much of the available clinical data come from trials conducted in Europe, where it is now classified as a “symptomatic slow-acting drug in osteoarthritis” (SYSADOA) (23). Some have suggested that it may also have chondroprotective properties and thereby have properties of a “disease-modifying antiosteoarthritic drug” (DMOAD). Among physicians in the United States, however, there is considerable skepticism, and its role in the treatment of OA, if any, remains very controversial.

Most of the clinical experience with chondroitin sulfate has been in knee OA, which is an important patient subset due to its prevalence and resulting disability. Radiographic evidence of knee OA is present in approximately one-third of people older than 65 years, although not all have symptoms. Epidemiologic studies suggest that knee OA increases in frequency with each decade of life and affects women more often. Obesity, prior trauma, and repetitive occupational knee bending have also been identified as risk factors. The functional consequences of knee OA are considerable, as it produces disability as often as heart and chronic obstructive pulmonary disease (24).

The initial management of OA includes patient education, weight reduction, aerobic exercise, and physical therapy, and these should always be pursued before pharmacologic intervention is considered. Weight reduction and strengthening exercises may be of particular benefit in knee OA. Acetaminophen and nonsteroidal anti-

inflammatory drugs (NSAIDs) are the agents most often prescribed when nonpharmacologic measures prove insufficient. Local intervention with intra-articular corticosteroid injections and viscosupplementation may be of benefit in some patients.

Most rheumatologists would agree that present therapies for OA are suboptimal for the majority of patients. This was readily apparent in a representative two-year clinical trial comparing an NSAID and acetaminophen in knee OA, in which a majority of participants in both treatment groups withdrew prior to study completion because of toxicity or lack of efficacy. Given the shortcomings of standard therapy, it is not surprising that more than one-third of patients report that they have experimented with alternative and complementary treatments (25).

Nutraceuticals are produced and distributed in the United States under the authority of the Dietary Supplement Health and Education Act (DSHEA), which was enacted in 1994 as an amendment to the existing Federal Food, Drug, and Cosmetic Act. The provisions of DSHEA broaden the definition of dietary supplements and have removed the more stringent premarket safety evaluations that had been required previously. The act stipulates that the labels of dietary supplements list ingredients and nutritional information and permits manufacturers to describe the supplement’s effect on the “structure or function” of the body and the “well-being” that might be achieved through its use. However, representations regarding the use of the supplement to diagnose, prevent, treat, or cure a specific disease are expressly prohibited.

Legislation passed by the U.S. Congress in 1991 and 1993 (P.L. 102–170 and P.L. 103–43, respectively) established an office within the National Institutes of Health “to facilitate the study and evaluation of complementary and alternative medical practices and to disseminate the resulting information to the public.” This Office of Alternative Medicine became the forerunner of the present National Center for Complementary and Alternative Medicine (NCCAM), which was formally instituted in February 1999. With a present budget of more than \$125.5 million, the stated mission of NCCAM is to “explore complementary and alternative healing practices in the context of rigorous science.” One of the first clinical trials to be sponsored by NCCAM was GAIT, a Phase III evaluation of the efficacy and safety of glucosamine and chondroitin sulfate in knee OA.

Much of the clinical experience and study data with chondroitin sulfate suffers from poor study design, possible sponsor bias, inadequate concealment, and lack of intention-to-treat principles. More recent studies have sought to address these issues with larger trials that are more rigorously designed. Under the sponsorship of NCCAM, GAIT was a multicenter, randomized, double-blind, and placebo-controlled trial designed to evaluate the tolerability and efficacy of glucosamine and chondroitin sulfate in the treatment of knee OA (26). The study assigned 1583 patients to five treatment arms that consisted of glucosamine alone, chondroitin sulfate alone, a combination of glucosamine and chondroitin sulfate, celecoxib, and placebo. This trial was a two-part study designed to compare the efficacy of glucosamine and chondroitin sulfate alone and in combination with that of an active comparator (celecoxib) and placebo in alleviating

the pain of knee OA over 24 weeks. An ancillary study on a subset of GAIT patients was developed to determine whether radiographic benefit was evident after 24 months of agent exposure.

Overall, GAIT results revealed no difference in response to chondroitin sulfate alone or in combination with glucosamine. However, in the subgroup of patients with moderate-to-severe pain, there was a significantly higher rate of response with combined therapy. In addition, a statistically significant improvement in joint effusion was noted in the chondroitin sulfate group among the secondary outcome measures. Hochberg et al. (27) conducted a post hoc analysis of the GAIT data that specifically addressed the effects of chondroitin sulfate on joint swelling, and concluded that the patients with earlier disease based on symptoms and radiographic stage were most likely to benefit.

Two meta-analyses published in 2007 evaluated the recent data for the use of chondroitin sulfate for pain relief in OA (28,29). The first meta-analysis assessed randomized controlled trial (RCT) data on several medications used for short-term pain control in OA including NSAIDs, opioid analgesics, paracetamol, intra-articular steroids, glucosamine, and chondroitin sulfate (28). Data on chondroitin sulfate was limited to six RCTs (362 patients) and demonstrated a small effect on pain relief at four weeks that was statistically significant. Interestingly, a secondary outcome measure of pain relief at three months after the start of treatment showed a slight improvement in pain relief between weeks 4 to 12. This outcome differed from all other therapeutic interventions that showed no change or a decrease in pain relief from week 4 to 12. However, five of the six studies were sponsored by pharmaceutical companies, and the remaining trial did not show improvement in pain relief at 12 weeks. Overall, none of the available medications evaluated in this meta-analysis met criteria for a clinically relevant change in the primary outcome.

The second meta-analysis evaluated the use of chondroitin sulfate for pain in OA of the knee or hip as the primary objective (29). Joint space narrowing effects were analyzed as a secondary objective. Though a statistically significant effect size for pain relief was reported using the 20 trials (3846 patients) included in the analysis, this effect size approached zero when only the three larger trials with adequate concealment and intent-to-treat data were included in the analysis (1553 patients). Five studies reported data on joint space narrowing, and upon analysis showed a significantly lower rate of joint space loss with chondroitin sulfate over placebo. Though the effect size was statistically significant, it was small and of unclear clinical significance.

The first meta-analysis concluded that chondroitin sulfate was likely beneficial in alleviating the symptoms of knee OA to some degree but felt that the magnitude of the clinical effect was most likely less than that reported (28). The second meta-analysis determined that data from the larger, more rigorous trials suggested that symptomatic benefit from chondroitin sulfate was modest to nonexistent (29). Few trials addressing the effect of chondroitin sulfate on joint space narrowing were available for the latter analysis, and though a small effect was detected, the authors concluded that it was of uncertain clinical relevance and more study was necessary (29).

The ancillary radiographic report from GAIT published by Sawitzke et al. (30) assessed 572 patients with knee OA followed for two years for radiographic progression. These patients had been randomized to receive glucosamine 500 mg three times daily, chondroitin sulfate 400 mg three times daily, the combination of both supplements, celecoxib 200 mg daily, or placebo as part of the original GAIT study and were followed over 24 months with the primary outcome measure of mean change in joint space width (JSW) using metatarophalangeal semi-flexed radiography (31). No statistically significant difference in the loss of JSW in any of the treatment groups was found compared to placebo, but the study was limited by the smaller sample size and smaller than expected loss in JSW. Interestingly, loss of JSW was greater in the combination group compared to those taking either glucosamine or chondroitin sulfate alone, leading the authors to raise the possibility of interference with combined use.

The recently published results of the Study on Osteoarthritis Progression Prevention assessed the effects of chondroitins 4 and 6 sulfate on radiographic progression as well as symptomatic relief in knee OA over a two-year period (32). This study randomized 622 patients to receive 800 mg of chondroitin sulfate or placebo daily for two years. Loss in minimum JSW was the primary outcome, and symptomatic relief was a secondary outcome. A significant reduction in JSW loss was observed in the chondroitin sulfate group. This group also showed faster improvement in pain over the first nine months, but no significant difference was observed between the two groups thereafter or at the end of the two years.

It is important to recognize that OA trials designed to evaluate radiographic progression, may not be appropriate for detecting the symptomatic benefits of an intervention. Additionally, interventions that result in slowing of radiographic progression may not relieve symptoms, or symptom relief may not correlate with improvements in radiographic progression. Because OA is generally a slowly progressive disease, modification of the disease by an intervention such as chondroitin sulfate may not be evident for many years. Though some trials may report statistically significant changes in radiographic progression, the clinical importance of these changes remains uncertain and may become apparent with longer observational periods.

SAFETY

Information regarding the safety of chondroitin sulfate as a single agent, or in combination with other agents, suggests that adverse effects associated with chondroitin sulfate use are both minor and infrequent. In the randomized, controlled trials summarized above, the frequency of adverse effects reported in the chondroitin sulfate treatment arms was no greater than that with placebo arms. The side effects reported most often with chondroitin sulfate were epigastric distress, diarrhea, and constipation. Additionally, rashes, edema, alopecia, and extrasystoles have been reported, though infrequently.

An additional safety concern is the potential for transmission of bovine spongiform encephalopathy (BSE, or mad cow disease) from infected beef products. Despite

stringent safeguards put in place by the U.S. Department of Agriculture that banned the import of beef products from any at-risk country, a case was reported in an American herd. Those who elect to take chondroitin sulfate should be familiar with the animal source from which it has been extracted and, if bovine, assure themselves that it has come from a disease-free herd.

RECOMMENDATIONS

Considerable published medical literature is available suggesting that chondroitin sulfate is well tolerated and safe. Though it may be of benefit in alleviating the symptoms of OA in select patients, data demonstrating clinically relevant improvements in OA symptoms with chondroitin sulfate are sparse. This should be considered in the overall context that none of the currently available drugs for treatment of OA have shown dramatic improvements in pain relief. There are recent data suggesting that chondroitin sulfate may have effects on radiographic progression, but only studies of several year duration and sufficient scientific rigor will be able to determine the clinical significance of these findings. In light of the large number of studies documenting the favorable safety profile of chondroitin sulfate, patients who report benefit and would like to continue taking it can be assured that adverse effects are unlikely.

Chromium

Richard A. Anderson and William T. Cefalu

INTRODUCTION

Chromium (Cr) is the 13th most common element in the earth's crust and 26th most common element in seawater. It is present in the environment in oxidation states ranging from -2 to $+6$ but principally as metallic (Cr^0), trivalent ($+3$), and hexavalent ($+6$) Cr. The valence state in which the Cr is present in the environment is of critical importance. Trivalent Cr, the most common and naturally occurring form of Cr, is an essential nutrient with very low toxicity and is the subject of this entry. This review will also focus on the role of Cr in humans. Hexavalent, the form of Cr used for industrial purposes, is largely a man-made product formed by the oxidation of the naturally occurring trivalent Cr. It is highly toxic and does not occur normally in biological tissues. Low amounts of hexavalent Cr can be reduced in biological systems to trivalent Cr.

BIOCHEMISTRY AND PHYSIOLOGIC FUNCTIONS

Essentiality

Chromium was shown to be an essential element in humans during the 1970s when a patient on total parenteral nutrition (TPN) developed severe signs of diabetes including weight loss, glucose intolerance, and peripheral neuropathy that were refractory to insulin (1). Since conventional treatments for diabetes, including 45 units of insulin per day, were unsuccessful, the patient was given supplemental Cr based on previous animal studies and preliminary human studies. Following two weeks of supplemental Cr, signs and symptoms of diabetes were reversed and exogenous insulin requirements dropped from 45 units per day to 0. Beneficial effects of Cr on patients on TPN have been confirmed on numerous occasions and documented in the scientific literature from three separate laboratories (2–4). Chromium presently added to TPN solutions may not be adequate for some patients. Peripheral neuropathy and glucose intolerance of a patient receiving recommended levels of Cr in these TPN solutions (total parenteral intake approximately $15\text{ }\mu\text{g}$ daily) were alleviated by an additional $250\text{ }\mu\text{g}$ daily dose of Cr as Cr chloride. Peripheral neuropathy was improved significantly within four days of additional Cr and normalization of nerve conduction within three weeks. Glucose intolerance was also normalized within three weeks of supplemental Cr (5). Recently, a patient developed severe insulin resistance following surgical repair of a thoracic aorta aneurysm. Postoperatively, the patient required 2110 units of insulin for more than 40 hours while receiv-

ing pressors and glucocorticoids. After the administration of intravenous Cr at $3\text{ }\mu\text{g/hr}$, the blood sugar normalized and insulin therapy was discontinued (6). This case represents a unique approach using intravenous Cr to achieve glycemic control in a patient with extreme insulin resistance and acute critical illness. Chromium is routinely added to TPN solutions as a daily administration for adults of 10 to $15\text{ }\mu\text{g}$ and 0.14 to $0.20\text{ }\mu\text{g/kg}$ for pediatric TPN patients (4).

Signs of Deficiency

Signs and symptoms of marginal Cr deficiency are not limited to patients on TPN and may be widespread in the general population. Insufficient dietary intake of Cr leads to increases in risk factors associated with diabetes and cardiovascular diseases including elevated circulating insulin, glucose, triglycerides, total cholesterol, reduced high-density lipoprotein cholesterol (HDL-C), and impaired immune function (7,8).

Chromium was shown to be an essential nutrient for animals almost five decades ago when it was shown that rats that fed on a *Torula* yeast-based diet developed impaired glucose tolerance that was reversed by an insulin potentiating factor whose active component was shown to be trivalent Cr (9). Chromium has subsequently been shown to be an essential element for fish, mice, squirrel monkeys, guinea pigs, pigs, cattle, and humans (Table 1).

Absorption and Excretion

Absorbed Cr is excreted primarily in the urine and only small amounts are lost in the hair, perspiration, or bile. Therefore, urinary Cr excretion can be used as an indicator of Cr absorption. Chromium absorption is inversely related to dietary intake. At daily dietary intakes of $10\text{ }\mu\text{g}$, Cr absorption is approximately 2% and at intakes of $40\text{ }\mu\text{g}$ is 0.5% (11). This leads to absorption of approximately $0.2\text{ }\mu\text{g/day}$, which appears to be a minimal basal level. At dietary intakes above $50\text{ }\mu\text{g Cr/day}$, Cr absorption is approximately 0.4%. The form of Cr also influences the absorption, that is, absorption of Cr from Cr chloride is usually in the region of 0.4% and Cr from Cr picolinate (the most common Cr supplement) is approximately 1.2%. Chromium incorporation into rat tissues was shown to vary widely depending upon its form. The highest concentrations of Cr were found in the kidney followed by liver, spleen, heart, lungs, and gastrocnemius muscle (12). The absorption of nutritional forms of Cr by human subjects was shown to be the greatest for Cr as Cr histidinate followed by Cr picolinate, Cr methionate, and Cr pidolate (13). In addition to its form, oxidation state and route of

Table 1 Signs and Symptoms of Chromium Deficiency

Function	Species
Impaired glucose tolerance	Human, rat, mouse, squirrel monkey, guinea pig, cattle
Elevated circulating insulin	Human, rat, pig, cattle
Glycosuria	Human, rat
Fasting hyperglycemia	Human, rat, mouse
Impaired growth	Human, rat, mouse, turkey
Hypoglycemia	Human
Elevated serum cholesterol and triglycerides	Human, rat, mouse, cattle, pig
Increased incidence of aortic plaques	Rabbit, rat, mouse
Increased aortic intimal plaque area	Rabbit
Nerve disorders	Human ^a
Brain disorders	Human ^a
Corneal lesions	Rat, squirrel monkey
Increased ocular eye pressure	Human
Decreased fertility and sperm count	Rat
Decreased longevity	Rat, mouse
Decreased insulin binding	Human
Decreased insulin receptor number	Human
Decreased lean body mass	Human, pig, rat
Elevated percentage of body fat	Human, pig
Impaired humoral immune response	Cattle
Increased morbidity	Cattle

^aThese effects have been observed only in patients on TPN.

Source: From Ref. 10.

administration, ascorbic acid, carbohydrates, phytate, oxalate, aspirin, antacids, and indomethacin also alter Cr absorption. Ascorbic acid was shown to significantly increase Cr absorption in humans with similar results in rats (14). Using radioactively labeled Cr chloride, animals that were fed starch were shown to have higher Cr absorption than those fed on sucrose, fructose, or glucose (15). Phytate has been reported to have either no effect on Cr absorption or an inhibitory effect. Oxalate also inhibits Cr absorption. Prostaglandin inhibitors such as aspirin and indomethacin enhance Cr absorption, and antacids such as Maalox[®] (trade name of Vovartis, Fremont, MI) and Tums[®] (Glaxo Smith Kline, Research Triangle Park, NC) inhibit Cr absorption.

Glucose Intolerance and Diabetes

Chromium supplementation to the general public, and in participants with diabetes in particular, is widespread but the efficacy of supplemental Cr is controversial. The controversy surrounding Cr supplementation stems from many factors, but the lack of definitive randomized trials is a major contributor. Specifically, many of the earlier studies evaluating Cr were open label and therefore generated substantial bias. Additional concerns from these earlier studies were the lack of "gold standard" techniques to assess glucose metabolism (e.g., euglycemic-hyperinsulinemic clamps), the use of differing doses and formulations, and the study of heterogeneous study populations. Based on these concerns, conflicting data have been reported that have contributed greatly to the confusion among health care providers regarding the routine use of Cr as a dietary supplement. More recent evidence, however, supports the concept that Cr supplementation yields more consistent clinical effects on carbohydrate

metabolism particularly when consumed at higher doses, for example, 200 µg or greater daily consumption (7,8,16–18). Subjects with varying levels of blood lipids have also been shown to improve following Cr supplementation, with the greatest improvements in total cholesterol, HDL cholesterol, and triglycerides in subjects with the highest initial levels. In the past decade, Cr has been shown to improve the signs and/or symptoms of diabetes in people with glucose intolerance and type 1, type 2, gestational and steroid-induced diabetes. The amounts of supplemental Cr shown to have beneficial effects in these studies ranged from 200 to 1000 µg/day. In a double-blind placebo-controlled study involving 180 subjects with type 2 diabetes mellitus, Cr effects were greater at 1000 µg/day than at 200 µg/day (19). The most dramatic improvements were shown in hemoglobin A_{1C} (HbA_{1C}), which is a reliable indicator of long-term glucose control. HbA_{1C} in the placebo group was 8.5 ± 0.2%, 7.5 ± 0.2% in the 200 µg group, and 6.6 ± 0.1% in the group of subjects receiving 1000 µg of Cr as Cr picolinate per day for four months (the upper level of reference range is approximately 6.5%). Similar results were observed in a double-blind placebo-controlled crossover study involving 50 subjects with type 2 diabetes supplemented with 200 µg of Cr twice daily as Cr picolinate (20). Improvements in fasting insulin levels and one-hour glucose and insulin levels following a 100 g glucose tolerance test in women with gestational diabetes were greater in the group receiving 8 µg/kg body weight per day compared with those receiving 4 µg/kg body weight (21). Steroid-induced diabetes that could not be controlled by oral hypoglycemic medications and/or insulin was also improved to acceptable levels in 47 of 50 people given 600 µg of Cr as Cr picolinate per day for two weeks followed by a daily Cr maintenance dose of 200 µg (22,23). Insulin sensitivity of obese subjects with a family history of diabetes also improved following 1000 µg of supplemental Cr daily as Cr picolinate (17).

A combination of Cr and biotin (600 µg as Cr picolinate and 2 mg of biotin) led to significant decreases in HbA_{1C} and glucose compared with the placebo group in a double-blind study involving 348 subjects with type 2 diabetes mellitus (DM). In subjects with high cholesterol and type 2 DM, there were also significant improvements in total cholesterol and low-density lipoprotein cholesterol (LDL-C) levels and atherogenic index in the group consuming the Cr biotin combination. Significant decreases in LDL-C, total cholesterol, HbA_{1C}, and very low-density cholesterol levels were also observed in the Cr biotin group taking statins (24). In a related study involving poorly controlled subjects with type 2 DM, there was a significantly greater reduction in the total area under the curve for glucose during a two-hour glucose tolerance test in the group receiving the Cr biotin combination. There were also reductions in fructosamine, triglycerides, and triglycerides/HDL-C ratio (25).

Chromium was found to be the most often studied nutritional supplement in type 2 diabetes (26). MEDLINE and EMBASE databases were searched using a systematic approach. Only double-masked randomized controlled trials were selected. A majority of the trials found a positive effect of Cr on fasting plasma glucose. Studies have involved individual case studies to studies with more than

800 subjects for more than one year (27). However, a meta-analysis of published studies on the effects of Cr on glucose and insulin (18) concluded, based upon the studies analyzed, that there were no significant effects of Cr. However, several positive studies were not included in this analysis owing to lack of specific data and inability to have an access to the original data. Several studies not reporting beneficial effects of supplemental Cr involved healthy normal subjects, with good glucose tolerance, who would not be expected to respond to additional Cr (8). Response to Cr is also dependent upon the amount and form of Cr consumed, and studies involving 200 μg of Cr or less or a form of Cr that is poorly absorbed would also not be expected to demonstrate effects of supplemental Cr (8).

In an attempt to determine who responds to supplemental Cr, 73 subjects with type 2 diabetes mellitus were assessed in a double-blinded, randomized, placebo-controlled study (28). Subjects were assessed at baseline for glycemic control with glycated hemoglobin measures, oral glucose tolerance tests, and body weight and body fat measures (dual-energy X-ray absorptiometry). The only subject variable significantly associated with the clinical response to Cr was the baseline insulin sensitivity, as assessed with the hyperinsulinemic-euglycemic clamp [partial $R(2) = 0.4038$] ($P = 0.0004$). Subject phenotype appears to be very important when assessing the clinical response to Cr because baseline insulin sensitivity was found to account for nearly 40% of the variance in the clinical response to Cr (28).

A follow-up study with use of "state-of-the-art" metabolic techniques and in a well-characterized cohort of individuals with type 2 diabetes representing a wide range of both phenotype and parameters assessing whole body insulin action, suggested that a consistent effect of Cr to improve insulin action and glycemia was not observed. However, this study is the first to show that Cr levels after supplementation do not differ between "responders" and "nonresponders," and provides the first comprehensive assessment of physiological and biochemical characteristics of individuals who responded to Cr. Specifically, "response" to Cr is more likely in insulin-resistant individuals who have more elevated fasting glucose and A_{1C} levels. Another novel finding was that tissue lipids are decreased in subjects randomized to Cr. Thus, it may be postulated that Cr alters insulin sensitivity through modulation of lipid metabolism in peripheral tissues and may represent a unique mechanism of action for trace minerals. The mechanism for this effect is the focus of ongoing studies (29).

Antioxidant Effects

Increased oxidative stress in relation to abnormal glucose metabolism is well documented in people with diabetes (30,31), and the antioxidative effects of Cr have also been demonstrated in animal studies (32). Chromium has also been shown to function as an antioxidant in people with type 2 diabetes (33) and confirmed in subjects with type 2 diabetes with HbA_{1C} values greater than 8.5% (34). Following six months of supplementation with Cr and Cr in combination with the antioxidant vitamins, C and E, there were significant reductions in both groups in thiobarbituric reactive substances in a double-blind study involving adult subjects with type 2 diabetes and $HbA_{1C} >$

8.5%. Total antioxidative status and glutathione peroxidase levels were also higher in the Cr group and the Cr plus antioxidative vitamins group (35). In addition, fasting glucose, HbA_{1C} , and insulin resistance also improved in groups consuming Cr.

Weight and Lean Body Mass

While there are a number of animal and human studies that suggest an effect of supplemental Cr on increasing lean body mass and decreasing body weight, there are also a number of studies showing no detectable effects of supplemental Cr (36,37). It may take more than six months to detect changes in lean body mass in humans and there may not be an effect on total body weight, as increases in lean body mass and decreases in fat may lead to small or minimal changes in total weight. Future studies involving body weight and lean body mass should be for 24 weeks or longer and involve 400 μg of Cr or more daily. Additional studies shorter than 24 weeks will be of minimal benefit and will likely serve to cloud the issue of whether supplemental Cr has an effect on body composition and weight loss in humans (36). Beneficial effects of Cr on lean body mass in humans have been substantiated in studies with pigs (38). The lack of the effect of Cr on lean body mass has been presented (39). A meta-analysis reported a body weight reduction of 1.1 to 1.2 kg during an intervention period of 10 to 13 weeks of Cr supplementation, considered too small to be clinically significant (37). However, long-term administration studies should be performed to determine whether the reduction in body weight could be maintained.

The controversial area of Cr, weight, and lean body mass was clarified when it was shown that goats eating a diet high in refined carbohydrates ate more than those eating the diet supplemented with Cr (40,41). Increases in weight were attributed to the antilipolytic effects of insulin leading to accumulation of triglycerides in the adipose tissue. Elevated insulin levels in the low Cr animals would also lead to decreased glucagon. As glucagon stimulates lipolysis, decreased glucagon may lead to decreased lipolysis and subsequent accumulation of body fat and weight gain and may explain the effects on lean body mass in humans.

In the above-mentioned study involving goats, it also took more than 28 weeks to detect significant changes in body weight in rapidly growing goats. This is consistent with human studies, usually 12 weeks or less in duration, which are unable to detect significant changes in weight of people eating conventional diets with supplemental Cr.

Supplemental Cr, 1000 μg of Cr as Cr picolinate, was also shown to decrease food intake ($P < 0.0001$), hunger levels ($P < 0.05$), and fat cravings ($P < 0.0001$), and tended to decrease body weight ($P = 0.08$) in 42 overweight women who reported craving carbohydrates. Study design was double-blind placebo controlled (42). In a related study involving rats, intraperitoneal administration of Cr resulted in a subtle decrease in food intake but when administered centrally, Cr picolinate dose dependently decreased food intake. The authors concluded that Cr has a role in food intake regulation, which may be mediated by a direct effect on the brain (42).

Figure 1 Chromium decreases visceral fat, subcutaneous fat, and total fat. Thirty-seven people with type 2 diabetes mellitus (DM) were placed on sulfonylurea medication for three months followed by six months of either 1000 μ g of Cr as Cr picolinate per day or placebo. *Significantly different at $P < 0.05$; **significantly different at $P < 0.01$. FFA, free fatty acids. Source: Adapted from Ref. 43.

A well-controlled study by the same group demonstrated that weight gain in people with type 2 diabetes was clearly regulated by supplemental Cr (43). Thirty-seven subjects with type 2 diabetes were placed on sulfonylurea drugs to control blood sugar for three months and then randomized to receive either Cr or placebo. Subjects receiving the supplemental Cr had smaller increases in body weight, percent body fat, and total abdominal fat compared with those in the placebo group. Subjects receiving Cr also had increased insulin sensitivity, corrected for fat-free-mass, and decreased free fatty acids (Fig. 1) (43).

Depression

A small pilot study suggested that Cr might be effective in the treatment of atypical depression. The study involved 15 patients with major depression, was double-blind, randomized, and placebo controlled (44). Seventy percent of the subjects responded to Cr with no negative side effects. Traditionally, depression has been treated with monoamine oxidase inhibitors; the toxicity and side effects of this class of drugs represent major limitations and the response is usually 50% or less. Depression has been associated with insulin resistance (45) and it is conceivable that increased insulin sensitivity leads to an enhanced central noradrenergic and serotonergic activity. Postsynaptic brain serotonin receptor downregulation by Cr in humans has also been reported, which could relate to insulin sensitivity and depression (46). However, larger and more comprehensive studies are required to address this problem.

In a double-blind, multicenter, eight-week replication study, 113 adult outpatients with atypical depression were randomized 2:1 to receive 600 μ g/day of elemental Cr, as provided by Cr picolinate, or placebo (47). Primary efficacy measures were the 29-item Hamilton Depression Rating Scale (HAM-D-29) and the Clinical Global Impressions Improvement Scale (CGI-I). The main effect of Cr was on carbohydrate craving and appetite regulation in depressed patients demonstrating that 600 μ g of elemen-

tal Cr may be beneficial for patients with atypical depression who also have severe carbohydrate craving. Further studies are needed to evaluate Cr in depressed patients specifically selected for symptoms of increased appetite and carbohydrate craving as well as to determine whether a higher dose of Cr would have an effect on mood.

The involvement of glutamatergic and serotonergic receptors in the antidepressant-like activity of Cr has been demonstrated in mice (48). The study confirmed the antidepressant-like activity of Cr in the mouse forced swim test and indicates the major role of the α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptor and participation of N-methyl-D-aspartate (NMDA) glutamatergic and 5-HT (1) and 5-HT (2 A/C) serotonin receptors in this activity.

Mechanism

How Cr serves as a cofactor for insulin action is not fully understood, and Cr remains as one of the only traceable minerals where a specific mechanism of action has not been identified. Several in vivo and in vitro studies have postulated a potential mechanism, but it must be stated that this mechanism has not been studied as to whether this is applicable to in vivo states. However, a low-molecular-weight chromium-binding substance (LMWCr) termed chromodulin (MW \approx 1500 Da) has been described, which appears to be involved in mediating the intracellular effects of Cr. It is composed of glycine, cysteine, glutamic acid, and aspartic acid (49). The principal carrier protein for Cr in the blood is suggested to be transferrin, which also is suggested to play a critical role in movement of Cr from blood to LMWCr. It has been postulated that an initial step in this process is the migration of transferrin receptors (Tf-R) to plasma membranes of insulin-insensitive cells after insulin stimulation. Transferrin containing the bound Cr binds to the Tf-R and is internalized by endocytosis. The pH of the internalized vesicle is reduced by adenosine triphosphate-driven proton pumps, Cr is released from transferrin, and the resulting free Cr is postulated to be sequestered by LMWCr (49,50). With this step, Cr is transferred from transferrin to LMWCr, which normally exists in insulin-dependent cells in the apo, or inactive, form. Binding with Cr ions converts inactive LMWCr to its holo, or active, form. It is proposed that LMWCr then participates as part of an insulin signal amplification system as it binds to insulin-activated insulin receptors and results in stimulating its tyrosine kinase activity. The end result of this process is postulated to be the activation of insulin receptor kinase and potentiation of the actions of insulin. Importantly, LMWCr without bound Cr or in the presence of other metal ions has been shown to be ineffective in activating insulin-dependent kinase activity and thus enhancing the actions of insulin (51). Thus, although this is an attractive hypothesis, definitive data for this mechanism as to whether it is operative in humans is lacking.

Chromium has also been reported to modulate phosphotyrosine phosphatase (52), the enzyme that cleaves phosphate from the insulin receptor leading to decreases in insulin sensitivity. The balance between kinase and phosphatase activity is suggested to facilitate insulin's role in rapidly moving glucose into cells. In addition, it

has been suggested that Cr enhances insulin binding, insulin receptor number, insulin internalization, and β -cell sensitivity (8). All of these effects contribute to improved insulin sensitivity.

Chromium, like insulin, also stimulates mRNA and protein levels for Ca^{2+} -ATPase, a protein involved in calcium transport. A combination of insulin and Cr as Cr picolinate caused a greater stimulation of the Ca^{2+} -ATPase mRNA than either insulin or Cr alone (53). Fluorometric analysis of the rate of ionized calcium recovery following stimulation with arginine also showed an effect of Cr; Cr picolinate alone increased recovery rate of 35% and Cr plus insulin 133%, compared to the increased recovery rate of 83% caused by insulin alone. In skeletal muscle cells, Cr was shown to stimulate tyrosine phosphorylation of the insulin receptor and insulin receptor substrate 1 (54). Wang et al. (55) also reported increased phosphorylation of the insulin receptor and concluded that cellular Cr potentiates insulin signaling by increasing insulin receptor kinase activity, separate from inhibition of phosphotyrosine phosphatase. Elmendorf and colleagues conducted a series of studies demonstrating that the cholesterol content of the plasma membrane regulates the response to Cr (56–59). They reported that a loss of plasma membrane phosphatidylinositol 4,5-bisphosphate-regulated filamentous actin structure contributes to insulin-induced insulin resistance. They also reported that Cr picolinate augments insulin-regulated glucose transport in insulin-sensitive 3T3-L1 adipocytes by lowering plasma membrane cholesterol. Insulin-induced insulin-resistant adipocytes display elevated plasma membrane cholesterol with a reciprocal decrease in plasma membrane phosphatidylinositol 4,5-bisphosphate. This lipid imbalance and insulin resistance was corrected by the cholesterol-lowering action of Cr picolinate (57). The plasma membrane lipid imbalance did not impair insulin signaling, nor did Cr picolinate amplify insulin signal transduction demonstrating that plasma membrane cholesterol is involved in the response to Cr and may be important in subjects who respond to supplemental Cr. In summary, although the precise mechanism of action of Cr is not known, the data that are available suggest effects on the insulin signaling processes that may be regulated by plasma membrane cholesterol content.

INDICATIONS AND USAGE

Food Sources

Not only is the total dietary intake of Cr important but also the total diet consumed. For example, increased intakes of simple sugars lead to increased losses of supplemental Cr (60). This becomes a double-edged sword, as high sugar foods are often also low in Cr. Diets high in simple sugars lead to elevated levels of circulating insulin and once insulin increases, Cr is mobilized. Chromium does not appear to be reabsorbed by the kidney and is lost in the urine. Other stresses such as acute exercise, pregnancy and lactation, infection, and physical trauma also increase Cr losses (61).

Foods high in Cr that are also low in simple sugars include broccoli, green beans, apples, and high fiber breakfast cereals (62). When nonprocessed fruits, vegetables, and high fiber foods are consumed, the requirement

for Cr is postulated to be lower because the Cr losses are lower. Chromium content of foods cannot be calculated from food composition tables, as there are large variations in individual foods owing likely to the contamination that occurs during growing and processing.

REFERENCE INTAKES

The estimated safe and adequate daily dietary intake (ESADDI) for Cr for children aged seven years to adult of 50 to 200 $\mu\text{g}/\text{day}$ was established by committees of the US National Academy of Sciences in 1980 and affirmed in 1989 (63). The Food and Drug Administration proposed a Reference Dietary Intake for Cr effective in 1997 of 120 $\mu\text{g}/\text{day}$. The new committee of the National Academy of Sciences has established that the normal intake of Cr should serve as the adequate intake of 20 μg for women and 30 μg for men older than 50 years and 25 μg for women and 35 μg for men aged 19 to 50 years (Table 2). It is unclear why the adequate intake for Cr is lower for people older than 50 years, other than total caloric intake. It is recognized that Cr is a cofactor for insulin action, and insulin action is known to be diminished with aging, but unsure whether this is a major reason. Indices of Cr status such as the Cr content of hair, sweat, and urine were shown to decrease with age in a study involving more than 40,000 people (64).

The proposed adequate intake appears to be the average intake as reported in 1985, which appears to be sub-optimal. Average daily intake (mean \pm SEM) of subjects consuming normal diets was 25 ± 1 μg for women and 33 ± 3 μg for men (11). There have been more than 30 studies reporting beneficial effects of supplemental Cr on people with blood glucose values ranging from marginally elevated to glucose intolerance and diabetes when consuming diets of similar Cr content.

Consumption of controlled normal diets in the lowest quartile of normal Cr intake, but near the new adequate intakes, led to detrimental effects on glucose (Fig. 2) in subjects with marginally impaired glucose

Figure 2 Effects of dietary Cr on people with good glucose tolerance and those with marginally impaired glucose tolerance consuming 20 μg or less of Cr daily. Subjects with good glucose tolerance, controls, are subjects with blood glucose levels less than 5.5 mmol/L (100 mg/dL), 90 minutes after consuming an oral glucose load of 1 g/kg body weight. Subjects defined as marginally hyperglycemic have 90-minute glucose levels between 5.5 and 11.1 mmol/L following an oral glucose load of 1 g/kg. Bars with different superscripts are significantly different at $P < 0.05$. Subjects with good glucose tolerance are able to maintain normal glucose levels at these low intakes, but not subjects with varying degrees of glucose intolerance. Source: From Ref. 66.

tolerance [90-minute glucose between 5.5 and 11.1 mmol/L (100–200 mg/dL) following an oral glucose load of 1 g/kg body weight]. The average person older than 25 years has blood glucose in this range. Consumption of these same diets by people with good glucose tolerance (90-minute glucose less than 5.5 mmol/L) did not lead to changes in glucose and insulin variables. This is consistent with previous studies demonstrating that the requirement for Cr is related to the degree of glucose intolerance and demonstrates that an intake of 20 μg /day of Cr is not adequate for people with marginally impaired glucose tolerance and certainly not for those with impaired glucose tolerance or diabetes.

ADVERSE EFFECTS

Safety of Chromium

Trivalent Cr, the form of Cr found in foods and nutrient supplements, is considered as one of the least toxic nutrients. The reference dose established by the US Environmental Protection Agency for Cr is 350 times the upper limit of the ESADDI as established in 1980 and affirmed in 1989, 3500 times the new adequate intake for women and 2333 times for men. The ratio of the reference dose to the required levels for most mineral and trace minerals is less than 10. The reference dose is defined as an estimate (with uncertainty spanning perhaps an order of magnitude) of a daily exposure to the human population, including sensitive subgroups, that is likely to be without an appreciable risk of deleterious effects during a lifetime. With these large safety factors, it is highly unlikely that there would be any reproducible signs of Cr toxicity at daily supplementation ranges of 1000 μg or less. There has been no evidence of toxicity in any of the nutritional studies involving Cr supplementation, but there have been

individual case studies reporting detrimental effects that have not been confirmed (67). Since the absorption of Cr is very low, it is likely that there would be indigestion and vomiting before enough Cr was absorbed to cause toxicity. However, Cr does bind to many biological substances including DNA and, at high enough levels, could (like almost all nutrients) lead to signs of toxicity in sensitive individuals. The toxic effects of Cr under nonphysiological conditions have been reviewed (39). The National Toxicology Program (NTP) (68) has completed independent in vitro and in vivo genotoxicity assays and evaluation of Cr picolinate, the most popular form of Cr in nutrient supplements, demonstrating that Cr picolinate did not produce chromosome damage in in vivo mouse assays and had no effect in two bacterial mutation assays (69). The absence of negative effects of Cr picolinate as reviewed by the NTP has led to the addition of Cr picolinate to generally recognized as safe list (68,69). Owing to the low toxicity of trivalent Cr, there is no upper limit established for Cr in the new National Academy of Sciences Guidelines (65).

CONCLUSIONS

The effects of Cr on glucose and insulin metabolism are well documented. Normal dietary intake of Cr appears to be suboptimal because several studies have reported beneficial effects of Cr on people with elevated blood glucose or type 2 diabetes eating conventional diets. Stresses that alter blood glucose often lead to increased mobilization of Cr that is subsequently lost from the body via the urine. The mechanism of action of Cr is largely through improvements in insulin sensitivity. Chromium makes insulin more effective and in the presence of Cr in a useable form, lower levels of insulin are required. There is no established upper limit for the supplemental Cr as it has very low toxicity and there have been no documented negative side effects in any of the more than 35 clinical studies. Number of subjects per study ranged from less than 10 to more than 800.

Coenzyme Q₁₀

Gustav Dallner and Roland Stocker

INTRODUCTION

Coenzyme Q is a lipid with broad distribution in nature, present in plants, bacteria, fungi, and all animal tissues. Coenzyme Q refers to a general structure composed of a nucleus, that is, 2,3-dimethoxy-5-methylbenzoquinone, and, substituted at position 6 of this quinone, a side chain consisting of isoprene units (5 carbons), all in trans configuration and with one double bond. In human tissues, the major part of coenzyme Q is coenzyme Q₁₀, which has 10 isoprene units; only 2% to 7% is present as coenzyme Q₉.

NAME AND GENERAL DESCRIPTION

Coenzyme Q₁₀ (C₅₉H₉₀O₄) has a molecular weight of 863.3, melting point of 49°C, and redox potential of around +100 mV. The lipid is soluble in most organic solvents but not in water. The term coenzyme Q refers to both oxidized and reduced forms.

The oxidized form of coenzyme Q, ubiquinone (CoQ), has an absorption maximum at 275 nm, whereas its reduced form, ubiquinol (CoQH₂), has a small maximum at 290 nm. The absorption of CoQ at 210 nm is six times higher than that at 275 nm, but absorption at 210 nm is not specific for CoQ; this reflects the double bonds of the polyisoprenoid moiety and is therefore unspecific. The two major features of the lipid are the quinone moiety and the side chain. The quinone moiety is the basis for the redox function of this coenzyme, allowing continuous oxidation reduction (Fig. 1) as a result of enzymatic actions. The long polyisoprenoid side chain gives the molecule its highly hydrophobic character and influences its physical properties and arrangement in membranes.

EXTRACTION AND ANALYSIS

For analysis of the blood and tissue level of coenzyme Q, extraction is usually performed with organic solvents without previous acid or alkaline hydrolysis (1). The simplest procedure is using petroleum ether, hexane, or isopropyl alcohol and methanol. In this system, phase separation occurs, and the methanol phase retains all the phospholipids, which make up more than 90% of the total lipid in most tissues. The separated neutral lipids, among them coenzyme Q, are generally isolated and quantified by reversed phase high-performance liquid chromatography (HPLC) and UV detection. Both the sensitivity and the specificity of the method can be improved greatly by using electrochemical detection. In addition, this lat-

ter procedure makes it possible to analyze—under certain conditions—the ratio of oxidized/reduced coenzyme Q amount, reflecting the in vivo situation.

BIOCHEMISTRY AND FUNCTIONS

Biosynthesis

The biosynthesis of coenzyme Q in animal and human tissues is unique though the initial section, designated the mevalonate pathway, is identical for the production of coenzyme Q, cholesterol, dolichol, and isoprenylated proteins (2). After the branch point, however, the terminal portions of the biosynthetic pathways for each of the products are specific (Fig. 2).

The mevalonate pathway consists of eight enzymatic reactions, which lead to the production of farnesyl pyrophosphate, the common initial substrate for all terminal products mentioned earlier. The pathway starts with two enzymatic steps using three molecules of acetyl-CoA, resulting in 3-hydroxy-3-methylglutaryl-CoA (HMG-CoA). The next reaction is a reduction to mevalonate by HMG-CoA reductase. This reaction is considered to be the main regulatory step in the pathway and also in cholesterol synthesis. Statins, drugs very commonly used in the treatment of hypercholesterolemia, are competitive inhibitors of HMG-CoA reductase. Mevalonate is phosphorylated in two steps to mevalonate pyrophosphate, which is then decarboxylated to isopentenyl pyrophosphate. Isopentenyl pyrophosphate is not only an intermediate but also the main building block for the synthesis of dolichol and the side chain of coenzyme Q. It is isomerized to dimethylallyl pyrophosphate, the substrate for farnesyl synthase. This enzyme mediates a two-step reaction, giving rise initially to the enzyme-bound, two-isoprenoid intermediate geranyl pyrophosphate, followed by a new condensation with isopentenyl pyrophosphate to the three-isoprenoid farnesyl pyrophosphate.

All branch-point enzymes utilize farnesyl pyrophosphate as substrate and they initiate the terminal part of the synthesis. These enzymes are considered for overall rate limiting and are consequently of utmost importance in the regulation of the biosynthesis of the lipid in question. In cholesterol synthesis, squalene synthase mediates the head-to-head condensation of two molecules of farnesyl pyrophosphate. *cis*-Prenyltransferase catalyzes the 1'-4 condensation of *cis*-isopentenyl pyrophosphate to all-trans farnesyl pyrophosphate, which, after additional modifications, generates dolichols with chain length between 16 and 23 isoprene units. *trans*-Prenyltransferase mediates a series of addition reactions of isopentenyl

Figure 1 Coenzyme Q₁₀, shown in its reduced ubiquinol-10 (top) and oxidized ubiquinone-10 (bottom) forms, consists of a long hydrophobic side chain and a substituted benzoquinone ring.

pyrophosphate to farnesyl pyrophosphate, resulting in all-trans polyprenyl pyrophosphate, giving the side chain of coenzyme Q. The chain length varies between different species, and in humans, the chain is mostly decaprenyl pyrophosphate, with some solanesyl pyrophosphate.

The next step in the biosynthesis requires the precursor of the benzoquinone moiety, 4-hydroxybenzoate, which itself is produced from tyrosine and is present in excess amounts. After prenylation of 4-hydroxybenzoate, the ring is modified by C-hydroxylations, decarboxylation, O-methylations, and C-methylation. The final product of the biosynthetic process is reduced coenzyme Q, ready to serve as electron donor. The sequence of these reactions has been studied so far mainly in bacteria and yeast. In mammalian tissues, several genes have been identified through complementary recognition with yeast and the function for some of them was also established. Isolated enzymes are not available at present, although these will be required for the establishment of the details of coenzyme Q synthesis in animal tissues.

Enzymatic Reduction of CoQ

A major function of coenzyme Q is to serve as a lipid-soluble antioxidant. This requires CoQ to be present in its reduced form, CoQH₂, raising the question of how CoQ is maintained in its reduced form, CoQH₂. Ascorbate readily reduces benzoquinone in a catalytic process controlled by molecular oxygen, although this reduction is not likely of biological importance, as the benzoquinone moiety of the lipid-soluble CoQ₁₀, when localized in biological membranes, is not accessible to the water-soluble vitamin C. Similarly, cytosolic DT-diaphorase, an enzyme proposed earlier for CoQ₁₀ reduction, is not efficient in reducing benzoquinones containing long isoprene side chains. Based on studies with the inhibitors rotenone and dicoumarol, it is suggested that a cytosolic reduced nicotinamide adenine dinucleotide phosphate (NADPH)-dependent CoQ reductase, different from the mitochondrial reductase and DT-diaphorase, is involved. More recently, the flavin adenine dinucleotide (FAD)-containing enzymes, lipoamide dehydrogenase and thioredoxin reductase, were found to reduce CoQ in vitro with high efficiency. These enzymes are homodimers, have a molecular weight of around 55 kDa, and belong to the family of pyridine nucleotide disulfide oxidoreductases.

Enzymatic Functions

The most thoroughly studied function of coenzyme Q is its participation in the mitochondrial electron transport chain. The lipid is essential in respiration as it shuttles electrons from nicotinamide nucleotide-linked (NADH) dehydrogenase and succinate dehydrogenase (complexes I and II) to the cytochrome system (complex III). During respiration, coenzyme Q is present in fully oxidized, fully reduced, and semiquinone forms. In the protonmotive Q cycle, there is a cyclic electron transfer pathway through complex III involving semiquinone that accounts for the energy conservation at coupling site 2 of the respiratory chain.

An electron transport system is also present in the plasma membranes of cells for transferring electrons across the membrane (3). The system is composed of a quinone reductase located on the cytosolic side and is thought to reduce CoQ in the presence of NADH. The resulting CoQH₂ then shuttles electrons to an NADH oxidase, located on the external surface of the plasma membrane, that reduces extracellular electron acceptors such as the ascorbyl radical, in this case to ascorbate. This oxidase is not related to the NADPH oxidase of phagocytes, which functions independent of coenzyme Q. The precise

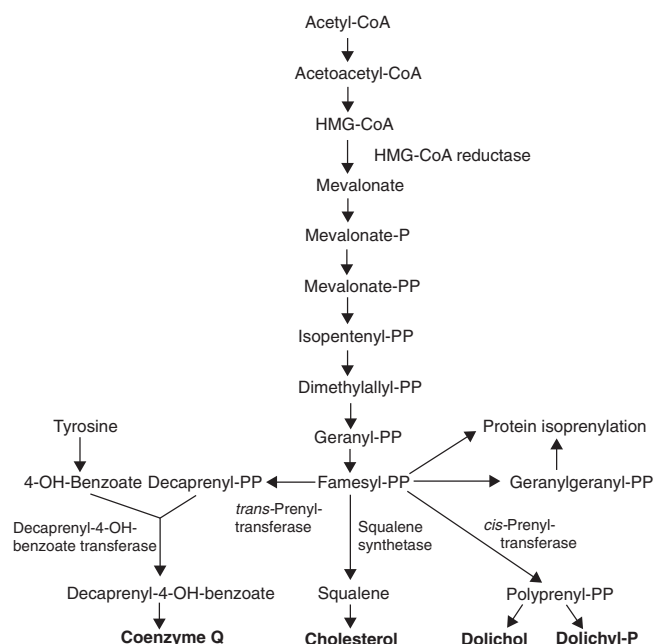

Figure 2 The mevalonate pathway leading to the biosynthesis of coenzyme Q, cholesterol, dolichol, and dolichyl phosphate.

function(s) of the NADH oxidase remain(s) to be elucidated, although it has been suggested to be involved in the control of cell growth and differentiation, the maintenance of extracellular ascorbic acid, the regulation of cytosolic NAD⁺/NADH ratio, the induction of tyrosine kinase, and early gene expression.

An electron transport system has also been proposed to be present in lysosomal membranes, transferring electrons from NADH to FAD, cytochrome *b*₅, CoQ, and molecular oxygen. This system could be involved in the translocation of protons into the lysosomal lumen.

Nonenzymatic Functions

Modulation of Mitochondrial Pore Opening

Ions and solutes may penetrate the inner mitochondrial membrane through specific transporters and ion channels. It has been observed *in vitro*, during the accumulation of Ca²⁺, that a permeability transition occurs and macromolecules up to the size of 1500 Da cross the membrane as a result of opening of an inner mitochondrial complex, the membrane transition pore. A large number of different compounds can open or close the membrane transition pore. An opening in the inner mitochondrial membrane is highly deleterious as it leads to loss of pyridine nucleotides, hydrolysis of adenosine triphosphate (ATP), disruption of ionic status, and elimination of the proton-motive force. Opening of the membrane transition pore is suggested to be an early event in apoptosis, causing activation of the caspase cascade through release of cytochrome *c*. On the other hand, the membrane transition pore may also have a physiological function by acting as a fast Ca²⁺ release channel in mitochondria.

Various coenzyme Q analogs that contain the benzoquinone moiety with or without a short saturated or unsaturated side chain are modulators of the membrane transition pore (4). They can inhibit, induce, or counteract the effects of inhibitors and inducers. Endogenous CoQ₁₀ may play an important role in preventing the membrane transition pore from opening, as it counteracts several apoptotic events, such as DNA fragmentation, cytochrome *c* release, and membrane potential depolarization.

Uncoupling Protein Function

It is well established that the inner mitochondrial membrane possesses uncoupling proteins that translocate protons from the outside to the inside of the mitochondria. As a result, the proton gradient established by the respiratory chain is uncoupled from oxidative phosphorylation and heat is produced instead of energy. In human tissues, five uncoupling proteins have been identified, but only uncoupling protein 1 has been studied in detail. It is present in brown adipose tissue and participates in thermogenesis. The content of uncoupling proteins in other tissues is low, since uncoupling is not a common event. Uncoupling protein 2 is found in most tissues, and uncoupling protein 3 is abundant in skeletal muscle.

By overexpressing uncoupling proteins 1, 2, and 3 from *Escherichia coli* in liposomes, it was demonstrated that coenzyme Q is an obligatory cofactor for the functioning of uncoupling proteins, with the highest activity obtained with CoQ₁₀ (5). Uncoupling proteins were able to transport protons only when CoQ₁₀ was added to the

membranes in the presence of fatty acids. Low concentration of ATP inhibited the activity. In this way, a proton is delivered from a fatty acid to the uncoupling protein with the assistance of CoQ₁₀ in the inner mitochondrial membrane. This is followed by the translocation of a proton to the mitochondrial matrix by the uncoupling protein.

Antioxidant Activity

Approximately 1% to 2% of the molecular oxygen consumed by mitochondria is converted to superoxide anion radical and hydrogen peroxide. In addition, reactive oxygen species are produced by other processes, including autoxidation reactions, and by the action of enzymes such as NADPH oxidases of phagocytes and other cells, mitochondrial monoamine oxidase, flavin oxidases in peroxisomes, and cytochromes P-450. Furthermore, nitric oxide, generated by nitric oxide synthases, can interact with superoxide and give rise to a number of reactive nitrogen species. These reactive species have the potential to damage lipids, proteins, and DNA, a process generally referred to as "oxidative damage." Antioxidants are enzymes, proteins, or nonproteinaceous agents that prevent the formation of reactive oxygen and nitrogen species, or remove these species or biomolecules that have been oxidatively damaged.

Coenzyme Q is the only lipid-soluble antioxidant synthesized endogenously (6). Its reduced form, CoQH₂, inhibits protein and DNA oxidation, but it is its effect on lipid peroxidation that has been studied in detail. Ubiquinol inhibits the peroxidation of cell membrane lipids and also that of lipoprotein lipids present in the circulation and in the walls of blood vessels. It has been suggested that CoQH₂ is a more efficient antioxidant than vitamin E, for two reasons. First, its tissue (but not blood) concentration exceeds several fold that of vitamin E. Second, and similar to vitamin C, CoQH₂ effectively reduces α -tocopheroxyl radical to α -tocopherol, and by doing so eliminates the potential pro-oxidant activities of vitamin E. In fact, CoQH₂ has been suggested to act as the first line of nonenzymatic antioxidant defense against lipid-derived radicals. In addition, CoQH₂ can inhibit the initiation of lipid peroxidation by scavenging aqueous radical oxidants.

As a result of its antioxidant action as a one-electron reductant, CoQH₂ is oxidized initially to its semiquinone radical (CoQH[•]), which itself may be oxidized further to CoQ, with the potential to generate the superoxide anion radical. Regeneration of CoQH₂ is therefore required for coenzyme Q to maintain its antioxidant activity. The effectiveness of cellular reducing systems is suggested by the fact that in most human tissues, the bulk of coenzyme Q is recovered as CoQH₂.

Effects on Atherosclerosis

Coenzyme Q₁₀ can theoretically attenuate atherosclerosis by protecting low-density lipoprotein from oxidation. Ubiquinol-10 is present in human low-density lipoprotein and, at physiological concentrations, prevents its oxidation *in vitro* more efficiently than vitamin E. The antiatherogenic effects are demonstrated in apolipoprotein E-deficient mice fed a high-fat diet (7). Supplementation with pharmacological doses of CoQ₁₀ not only increased aortic CoQ₁₀ levels but also decreased the absolute

concentration of lipoprotein-associated lipid hydroperoxides in atherosclerotic lesions. Most significantly, there was a clear decrease in the size of atherosclerotic lesions in the whole aorta. Whether these protective effects are solely due to the antioxidant actions of coenzyme Q remains to be established, as the tissue content of other markers of oxidative stress, such as hydroxylated cholesteryl esters and α -tocopherylquinone, did not decrease.

Oral administration of CoQ₁₀ to healthy humans results in increased concentrations of CoQ₁₀H₂ in circulating lipoproteins (8), with reduction most likely taking place in the intestine. Administration of CoQ₁₀ also results in uptake of the lipid into monocytes and lymphocytes but not into granulocytes, whereas this dietary treatment increases the vitamin E content in both mononuclear and polymorphonuclear cells (9). The phospholipid composition is modified selectively in mononuclear cells, which display elevated amounts of arachidonic acid. Basal and stimulated levels of β_2 -integrin CD11b and complement receptor CD35, distributed on the surface of monocytes, are also decreased by CoQ₁₀ supplementation. This may contribute to the antiatherogenic effect of dietary CoQ₁₀, since CD11b contributes to the recruitment of monocytes to the vessel wall during atherogenesis.

Effects on Blood Flow and Pressure

It is uncertain whether or not CoQ₁₀ reduces blood pressure in the long-term management of primary hypertension (10). It is possible that any blood pressure lowering effect is indirect—perhaps via improved diastolic and endothelial function. Endothelial dysfunction of the arteries has potentially serious consequences and is commonly seen in patients with established cardiovascular disease or elevated risk factors. Ubiquinone supplementation improves endothelial function measured as flow-mediated dilatation of the brachial artery in patients with uncomplicated type 2 diabetes and dyslipidemia but not in hypercholesterolemic subjects (11). In diabetic patients, CoQ₁₀ administration has also been found to decrease systolic blood pressure and HbA_{1C}, but not F₂-isoprostanes, suggesting that the protective effects may have been unrelated in the decrease of vascular oxidative stress.

Potential Anti-inflammatory Effects

There is some evidence that pharmacological doses of CoQ₁₀ may have anti-inflammatory effects *in vivo* under some conditions (12). This is an area worthy of further investigations, as inflammation is part of the etiology in many diseases, such as cardiovascular diseases, diabetes, and Alzheimer disease. An anti-inflammatory effect could help explain why positive health effects are reported in a number of investigations when uptake of the lipid into a specific organ was limited.

PHYSIOLOGY

Tissue Distribution

CoQ₁₀ is present in all human tissues in highly variable amounts (Table 1). The amounts are dependent on several factors, the most important under normal physiological conditions is the age (see sect. "Aging"). The highest amount is found in the heart (114 μ g/g wet weight) (13).

Table 1 Concentration of Coenzyme Q₁₀ in Different Adult Human Tissues

Tissue	CoQ ₁₀ (μ g/g tissue)
Brain	13
Thyroid	25
Lung	8
Heart	114
Stomach	12
Small intestine	12
Colon	11
Liver	55
Pancreas	33
Spleen	25
Kidney	67
Testis	11
Muscle	40

In the kidney, liver, muscle, pancreas, spleen, and thyroid, the CoQ₁₀ content is between 25 and 67 μ g/g, and in the brain, lung, testis, intestine, colon, and ventricle, it is between 8 and 13 μ g/g. This variation is explained by histological structure, and consequently there are great variations within the same organ. For example, in different regions of the bovine brain, the amount of CoQ₁₀ varies between 25 μ g/g (striatum) and 3 μ g/g (white matter). Rapid extraction and direct measurement by HPLC show that the major part of coenzyme Q₁₀ in tissues, with the exception of brain and lung, is the reduced form, CoQ₁₀H₂.

Intracellular Distribution

In rat liver, the highest amount of coenzyme Q₉ is found in the outer and inner mitochondrial membranes, lysosomes, and Golgi vesicles (1.9–2.6 g/mg protein); the concentration in plasma membranes is 0.7 μ g/g, and it is 0.2 to 0.3 μ g/g in the nuclear envelope, rough and smooth microsomes, and peroxisomes (Table 2) (13). The distribution pattern is quite different from that of other neutral lipids. For example, the major part of dolichol is localized in lysosomes, that of cholesterol in plasma membranes, and that of vitamin E in Golgi vesicles.

Within membranes, coenzyme Q₁₀ has a specific arrangement, with the decaprenoid side chain located in the central hydrophobic region, between the bilayer of phospholipid fatty acids. The functionally active group, the benzoquinone ring, is located on the outer or inner

Table 2 Concentration of Coenzyme Q₉ in Different Subcellular Organelles of Rat Liver

Organelle	CoQ ₉ (μ g/mg protein)
Nuclear envelope	0.2
Mitochondria	1.4
Outer membrane	2.2
Inner membrane	1.9
Microsomes	0.2
Rough microsomes	0.2
Smooth microsomes	0.3
Lysosomes	1.9
Lysosomal membrane	0.4
Golgi vesicles	2.6
Peroxisomes	0.3
Plasma membrane	0.7

surface of the membrane depending on the functional requirement. Because of this central localization, coenzyme Q₁₀ destabilizes membranes, decreases the order of phospholipid fatty acids, and increases permeability. These effects are in contrast to those of cholesterol, which is located adjacent to fatty acids on one side of the bilayer and that stabilizes the membrane, increases the order of its lipids, and decreases membrane permeability.

Transport

While the mevalonate pathway from acetyl-CoA to farnesyl pyrophosphate is mainly cytoplasmic, the terminal parts of coenzyme Q biosynthesis are localized in the mitochondria and endoplasmic reticulum (ER)-Golgi system. The mitochondrial inner membrane probably receives its lipid from the biosynthetic system associated with the matrix-inner membrane space. Newly synthesized very-low-density lipoproteins assembled in the ER-Golgi system also contain *de novo* synthesized coenzyme Q, which has to be synthesized at this location, like the other lipid and protein components of the lipoproteins. It is most probable that the various other cellular membranes also receive their constitutive coenzyme Q from the ER-Golgi system, as is the case with other lipids. Judging by studies in plants *in vivo* and with reconstituted cell-free systems, intracellular transport of coenzyme Q is a vesicle-mediated, ATP-dependent process, and cytosolic carrier proteins may also be involved.

Due to its hydrophobicity, the existence of a binding/transfer protein for coenzyme Q seems plausible, and recently saposin B has been suggested to serve this function (14). Aqueous saposin B was reported to extract and bind coenzyme Q dissolved in hexane to form a saposin B-coenzyme Q complex, with the lipid-binding affinity decreasing in the order: CoQ₁₀ > CoQ₉ > CoQ₇ >> α -tocopherol >> cholesterol (no binding).

Under normal conditions, all organs and tissues synthesize sufficient coenzyme Q, so that external supply is not required. Coenzyme Q present in small amounts in all circulating lipoproteins is derived from very-low-density lipoprotein newly synthesized and discharged by the liver. It likely functions as an antioxidant and protects lipoproteins, with restricted redistribution among them. In the case of dietary coenzyme Q, lipoproteins are the carriers in the circulation and interact with at least some types of tissues for cargo delivery. Thus, the situation differs from that of cholesterol, in which case several organs depend on external supply from the diet or the liver.

Bioavailability

Plasma

The uptake of coenzyme Q from the intestine occurs at a low rate, with only 2% to 4% of the dietary lipid appearing in the circulation. The uptake mechanism has not been studied so far but is probably similar to that of vitamin E and mediated by chylomicrons. In rats, dietary CoQ₁₀ appears as CoQ₁₀H₂ in mesenteric triacylglycerol-rich lipoproteins, which enter the circulation and are converted by lipoprotein lipase to chylomicron remnants, which are then cleared rapidly by the liver. Some of this diet-derived coenzyme Q reappears in the circulation, perhaps as a result of hepatic synthesis and release of very-

low-density lipoprotein. Depending on the diet, in healthy human controls the amounts of coenzyme Q in very-low-density, low-density, and high-density lipoproteins are 1.2, 1.0, and 0.1 nmol/mg protein, respectively. After dietary supplementation (3×100 mg CoQ₁₀/day for 11 days), the amounts are 3.2, 3.5, and 0.3 nmol/mg protein, respectively. These data are consistent with the notion that circulating coenzyme Q redistributes among lipoproteins to protect them against oxidation.

For most tissues, the low bioavailability of CoQ limits the ability of supplements to restore normal tissue levels of CoQH₂ where deficiency exist. There are several potential ways to approach this problem, including administration of the lipid in reduced form, and increasing bioavailability by either derivatization or administering CoQ in association with cyclodextrins. "Mitoquinone," a cationic modified form of CoQ attained by coupling to triphenylphosphonium and targeted to mitochondria to improve mitochondrial function, has received much interest recently (15). However, it is important to point out that mitoquinone is not a form of CoQ naturally occurring in human tissue, and the increase in superoxide production observed after uptake of mitoquinone into mitochondria is of potential concern (16). A potential alternative approach to increase CoQ in blood and tissues may be via drugs that stimulate the endogenous synthesis. This would not only elevate the amount of the lipid but possibly also direct it to the appropriate location. Polyisoprenoid epoxides in tissue culture and peroxisome proliferator-activated receptor- α agonists in rodents increase CoQ synthesis and amounts; however, no drug for this purpose is presently available for humans.

Blood Cells

Red blood cells contain very small amounts of coenzyme Q. In lymphocytes, the content of CoQ₁₀ is doubled after one week of dietary supplementation with this lipid, and this enhances both the activity of DNA repair enzymes and the resistance of DNA to hydrogen peroxide-induced oxidation (17). Two months of CoQ₁₀ supply to humans increases the ratio of T4/T8 lymphocytes (18), and an increase in the number of lymphocytes has been noted after three months of dietary supply of this lipid. Ten weeks of CoQ₁₀ administration to healthy subjects elevated the lipid content by 50% in monocytes, but no increase was observed in polymorphonuclear cells.

Tissues

There remains some controversy regarding the bioavailability of dietary coenzyme Q in different tissues. In rats, the liver, spleen, adrenals, ovaries, and arteries take up a sizeable amount of dietary coenzyme Q (19). Under normal physiological conditions, very limited uptake may also occur in the heart, pancreas, pituitary gland, testis, and thymus. No uptake is apparent in the kidney, muscle, brain, and thyroid gland. However, uptake into rat brain has been reported—possibly the outcome of the specific conditions employed. Similarly, in mice, some, but not all, investigators have reported uptake into tissues. Derivatization of coenzyme Q by succinylation and acetylation increases its uptake into blood but not into various organs.

What is clear is that under normal conditions, the bioavailability of dietary coenzyme Q in most tissues is

limited. This may be explained by its distribution and functional requirement. Under normal conditions, all cells synthesize sufficient lipid, so that external supply is not required. Exogenous coenzyme Q taken up by the liver does not appear in mitochondria, which house the bulk of this cellular lipid, but is found mainly in nonmembranous compartments, such as the lysosomal lumen.

The situation is, however, different in states of severe coenzyme Q deficiency. Genetic modifications causing low levels of coenzyme Q have serious consequences for neuronal and muscular function (20). In children with genetic coenzyme Q deficiency, dietary supplementation greatly alleviates pathological conditions and re-establishes mitochondrial and other functions. Limited studies with biopsy samples from patients with cardiomyopathy also indicate that the cardiac levels of coenzyme Q are decreased and may be increased by dietary supplementation with the lipid. Thus, it appears that uptake and appropriate cellular distribution of coenzyme Q occur if there is a requirement for the lipid.

Direct organ uptake of sizeable amounts is not necessarily the only way of action of coenzyme Q, as other redox-active substances can act by signaling, serving as primary ligands or secondary transducers. Thus, the presence of coenzyme Q in the blood may impact on the vascular system, the production of cytokines, the expression of adhesion molecules, and the production of prostaglandins and leukotrienes. The possibility that metabolites of coenzyme Q influence metabolic processes has not yet been investigated.

Catabolism

The short half-life of coenzyme Q, ranging between 49 and 125 hours in various tissues (Table 3), indicates that the lipid is subject to rapid catabolism in all tissues. The main urinary metabolites identified have an unchanged and fully substituted aromatic ring with a short side chain containing five to seven carbon atoms and a carboxyl group at the ω -end (21). Phosphorylated forms of these metabolites are also recovered from nonhepatic tissues. These water-soluble metabolites are transferred to the circulation and are excreted by the kidney through urine. In the liver, the coenzyme Q metabolites become conjugated to glucuronic acid for fecal removal via bile.

Table 3 Half-life of CoQ₉ in Rat Tissues

Tissue	Half-life (hr)
Brain	90
Thyroid	49
Thymus	104
Heart	59
Stomach	72
Small intestine	54
Colon	54
Liver	79
Pancreas	94
Spleen	64
Kidney	125
Testis	50
Muscle	50

Regulation of Tissue Coenzyme Q Content

In contrast to cholesterol, coenzyme Q does not appear to be subject to dietary or diurnal variations. However, a number of treatments decrease the content of the lipid in experimental systems. Administration of thiouracil, which inhibits thyroid gland function, decreases liver coenzyme Q. Oral administration of vitamin A also lowers hepatic coenzyme Q. In selenium-deficient rats, the coenzyme Q content of the liver is decreased by 50%, and the amount of the lipid is also lowered in the heart and kidney (but not muscle). A protein-free diet for three weeks lowers coenzyme Q content in the liver and heart but not in the kidney, spleen, and brain. As indicated earlier, HMG-CoA reductase controls cholesterol synthesis because the branch-point enzyme squalene synthase has a low affinity for farnesyl pyrophosphate, so that its pool size is the main regulatory factor (22). By contrast, the branch-point enzyme of coenzyme Q synthesis, *trans*-prenyltransferase, has a comparatively higher affinity for farnesyl pyrophosphate, so that a decrease in this substrate does not generally lower the rate of coenzyme Q synthesis. It appears, however, that the doses of statins employed for the treatment of hypercholesterolemia result in inhibition of synthesis, as the coenzyme Q concentration decreases in several tissues (23).

As mentioned earlier, the bioavailability of dietary coenzyme Q is limited. For this reason, it would be advantageous to find compounds that elevate tissue concentrations of coenzyme Q by increasing its biosynthesis. In rats and mice, treatment with peroxisomal inducers, such as clofibrate, phthalates, and acetylsalicylic acid, induces coenzyme Q synthesis in most organs and elevates its concentration in all subcellular organelles (24). The upregulation takes place by interaction with a nuclear receptor: peroxisomal proliferator receptor- α . This receptor interacts with a number of genes, resulting in the increased synthesis of several enzymes, many of them connected to lipid metabolism. However, peroxisomal proliferator receptor- α is poorly expressed in human tissue, and it is not known to what extent this transcription factor is involved in coenzyme Q metabolism. Agonists or antagonists to various nuclear receptors may be a future approach to the upregulation of coenzyme Q biosynthesis and its concentration in human tissues.

Hormones control coenzyme Q metabolism, but their method of action is not known in detail. Growth hormone, thyroxine, dehydroepiandrosterone, and cortisone elevate coenzyme Q levels in rat liver to various extents. A liver-specific increase of coenzyme Q occurs in rat and mice after two to three weeks stay in the cold room (+4°C). Vitamin A deficiency more than doubles the coenzyme Q level in liver mitochondria and more than trebles that in liver microsomes. Squalastatin 1, an inhibitor of squalene synthase, greatly increases coenzyme Q synthesis by increasing the farnesyl pyrophosphate pool and saturating *trans*-prenyltransferase.

COENZYME Q₁₀ DEFICIENCY

Genetic Disorders

Coenzyme Q deficiency is an autosomal recessive disorder that may present itself in the form of myopathy,

encephalopathy and renal disease, or ataxia (20). The myopathic form is characterized by substantial loss of muscle coenzyme Q, muscle weakness, myoglobinuria, ragged-red fibers, and lactic acidosis. Patients with encephalopathy and renal involvement possess a more general disease, with myopia, deafness, renal failure, ataxia, amyotrophy, and locomotor disability. In these cases, coenzyme Q is undetectable or present at very low levels in cultured fibroblasts. In the ataxic form of deficiency, weakness, cerebellar ataxia, cerebellar atrophy, seizures, and mental retardation dominate, and low levels of coenzyme Q are found in the skeletal muscle. Various types of mutations have been found to be responsible for decreased synthesis of CoQ (25). Most of the mutations are of the primary type, affecting proteins related to the biosynthesis of the lipid. COOQ1-PDSS1 and -PDSS2 (two subunits of decaprenyl diphosphate synthase), COOQ2 (decaprenyl-4-hydroxybenzoate transferase), COOQ8 (CABC1 or ADCK3, a putative protein kinase), and COOQ9 (nonidentified function) are genes established in this group. There are also secondary forms of deficiency caused by mutations in genes not involved in coenzyme Q biosynthesis. Mutations in APTX (encoding aprataxin) and ETFDH (multiple acyl-CoA dehydrogenase deficiency caused by defects in electron transfer flavoprotein or ETF-ubiquinone oxidoreductase) also result in CoQ deficiency.

The cases described in the literature probably represent extreme forms of coenzyme Q deficiency, seriously affecting mitochondrial functions. Moderate coenzyme Q deficiency is probably more common, though this requires verification by appropriate analysis of tissue biopsy samples. Unfortunately, the coenzyme Q content in blood often does not mirror the tissue concentration of the lipid, and it is highly desirable to develop methods to estimate moderate degrees of coenzyme Q deficiency. At present, diagnosis depends on measuring the coenzyme Q content in muscle biopsy samples, cultured fibroblasts, and lymphoblasts, or analyzing mitochondrial respiration and enzymes that require coenzyme Q as intermediate.

CoQ deficiency is of special interest since it is the only treatable mitochondrial disease and oral administration of CoQ re-establishes normal functions. Early diagnosis before development of clinical symptoms is of outmost importance since established kidney and brain damages may not be completely reversible. The treatment, however, stops the process and the improvement is dramatic as children leave the wheel-chair state and are able to perform various activities. The problem is that at present diagnosis requires a muscle biopsy and analysis of mitochondrial functions. This does not allow screening of larger populations. Therefore, development of simplified diagnostic procedures would be of great interest also for diagnosis of less severe cases, probably present in relatively high numbers.

Aging

In human organs, the coenzyme Q content increases three- to fivefold during the first 20 years after birth, followed by a continuous decrease, so that in some tissues the concentration may be lower at 80 years than at birth (Table 4) (26). The decrease is less pronounced in the brain, where

Table 4 Coenzyme Q₁₀ Content (μg/g) with Age in Human Organs and Human Brain

Human organs	Age				
	2 days	2 yr	20 yr	41 yr	80 yr
Lung	2.2	6.4	6.0	6.5	3.1
Heart	36.7	78.5	110.0	75.0	47.2
Spleen	20.7	30.2	32.8	28.6	13.1

White matter	5.0	5.0	4.9	2.0	
Cerebellum	13.2	13.0	12.9	11.0	

it mainly takes place between 70 and 90 years, and its extent, between 20% and 60%, depends on the localization. This pattern is different from that seen for other lipids. In most tissues, the content of cholesterol and phospholipids remains unchanged during the whole life period, whereas the amounts of dolichyl phosphate and especially dolichol increase greatly with age. It is unclear whether the decrease in coenzyme Q content is caused by its lowering in all or some selected cellular membranes or, alternatively, by other changes such as decreased number of mitochondria.

Cardiomyopathy

The uptake of dietary coenzyme Q into heart muscle is low in both rats and humans, but it may increase significantly in various forms of cardiomyopathy (27). A number of clinical trials performed during the last 30 years suggest that heart functional performance may be improved modestly by dietary coenzyme Q supplementation (28,29). In congestive heart failure, improvements have been reported for ejection fraction, stroke volume, and cardiac output. Patients with angina may respond with improved myocardial efficiency. Reperfusion injury, such as after heart valve replacement and coronary artery bypass graft surgery, includes oxidative damage, and treatment of patients with coenzyme Q prior to surgery may lead to decreased oxidative damage and functional improvement. However, the benefits reported have not been consistent, and despite the existence of a large body of literature, there remains a need for large, long-term, and well-designed trials to establish unambiguously whether CoQ₁₀ supplements are beneficial in the setting of cardiomyopathy and the failing heart.

Neurological Disorders

Judging by extensive animal studies, a number of neurological diseases involve mitochondrial dysfunction and oxidative stress. The positive effects obtained with coenzyme Q treatment in these models suggest that supplementation may also be beneficial in humans (30). Patients with early Parkinson disease were subjected to a trial

in which the placebo group was compared with groups supplemented for 16 months with coenzyme Q up to daily doses of 1200 mg. It was found that coenzyme Q slowed the progressive functional deterioration, with the best results obtained with the highest dose. Platelets from these patients had decreased coenzyme Q content and also showed reduced activity of mitochondrial complex I and complex II/III. The ratio of CoQ₁₀H₂ to CoQ₁₀ was also decreased in these platelets, indicative of the presence of oxidative stress. Upon supplementation, the CoQ₁₀ content in the platelets increased and complex I activity was also elevated. In Huntington disease, magnetic resonance spectroscopy detected increased lactate concentration in the cerebral cortex. Administration of CoQ₁₀ caused a significant decrease in lactate that reversed upon discontinuation of the therapy.

Deficiency of frataxin, a regulator of mitochondrial iron content, causes Friedreich ataxia. When patients with this disease were treated with coenzyme Q and vitamin E for six months, progression of their neurological deficits was slowed down, associated with an improvement in cardiac and skeletal muscle energy metabolism (31). Treatment of these patients with idebenone, an analog of coenzyme Q, reduced heart hypertrophy and improved heart muscle function. In several studies, patients with mitochondrial encephalopathy, lactic acidosis, and strokes (MELAS) displayed significant improvement after coenzyme Q or idebenone treatment (32). Several other trials were also performed during recent years with variable results. Since there are subtypes of individual neurodegenerative diseases, large numbers of patients are required to obtain reliable results, which is often difficult to accomplish.

Statin Therapy

Statins are the drugs most commonly used for the treatment of hypercholesterolemia, and, in addition to efficient cholesterol lowering, they also have anti-inflammatory activities. The basis for their use is that inhibition of HMG-CoA reductase decreases the farnesyl pyrophosphate pool to such an extent that squalene synthase, which catalyzes the terminal regulatory step in cholesterol synthesis, is no longer saturated, thereby inhibiting overall synthesis (22). It appears, however, that the extent to which the farnesyl pyrophosphate pool is decreased by therapeutic doses of the drug also affects the saturation of *trans*- and *cis*-prenyltransferases in spite of the fact that these latter enzymes have a higher affinity for farnesyl pyrophosphate. Consequently, synthesis of both coenzyme Q and dolichol is inhibited. Rats treated with statins exhibit decreased levels of coenzyme Q, dolichol, and dolichyl phosphate in heart and muscle, and the same is probably also true in humans. In humans, statin treatment significantly decreases blood coenzyme Q concentration (33), although the clinical significance of this phenomenon remains to be established. Various degrees of myopathy, myalgia, and rhabdomyolysis have been reported in statin-treated patients, and it is possible, but not proven, that these conditions are related to decreased muscle coenzyme Q content. Initial trials of CoQ₁₀ supplementation in patients with statin-induced myopathy have provided variable results (34). Given the widespread use of statins, it is important

that additional studies address a possible causal link between these side effects of statin treatment and altered tissue coenzyme Q content.

Exercise

During endurance exercise training, the coenzyme Q concentration increases in rat muscle on a weight basis due to an increase in mitochondrial mass. After four days of high-intensity training, the coenzyme Q content in the exposed muscles of healthy persons is unchanged (35). Supplementation (120 mg/day) doubles the coenzyme Q concentration in the plasma, but there is no change in the muscle content as judged by HPLC analysis of the tissue homogenate and isolated mitochondrial fraction in both control and trained subjects.

Dosage

So far, no toxic or unwanted side effects have been described for CoQ₁₀ supplements in humans, not even after ingestion in gram quantities. In most studies, 100 to 200 mg has been given per day in two doses. In genetic disorders, in the case of adults, the dose may increase to 300 mg/day and in neurological diseases, up to 400 mg/day or more. In the latter case, in the frame of large multicenter trials, doses up to 2400 mg have been supplied. A patent on the use of statins combined with coenzyme Q has expired recently, although this combined preparation has not been manufactured so far. Now it may be possible for the pharmaceutical industry to introduce capsules containing statins and coenzyme Q in order to decrease the potential for muscle damage. In this case, relatively low doses of CoQ₁₀ (e.g., 50 or 100 mg/day) appear to be appropriate.

Conjugated Linoleic Acid

Kristina B. Martinez, Arion J. Kennedy, and Michael K. McIntosh

INTRODUCTION

Conjugated linoleic acid (CLA) consists of a group of positional and geometric fatty acid (FA) isomers of linoleic acid (C18:2; *cis*-9, *cis*-12 octadecadienoic acid). CLA isomers are found naturally in ruminant meats and dairy products due to biohydrogenation of linoleic or linolenic acids in the rumen of these animals. Larger quantities of CLA are chemically synthesized for use in dietary supplements or fortified foods. Initially identified as a potential anticarcinogen, CLA has been reported to prevent obesity, diabetes, or atherosclerosis in different animal and cell models, depending on the doses, isomers, and models used. Potential mechanisms for preventing these diseases include inducing cancer cell apoptosis, increasing energy expenditure and delipidating adipocytes, increasing insulin sensitivity, or reducing aortic lesions. However, unequivocal evidence in human participants is still lacking. Ironically, potential side effects of CLA supplementation include chronic inflammation, insulin resistance, and lipodystrophy. Long-term, well-controlled clinical trials and more mechanistic studies are needed to better understand the true potential health benefits versus risks of consuming CLA isomers and their mechanisms of action.

CHEMISTRY AND SYNTHESIS OF CLA

Natural Synthesis of CLA Isomers

CLA isomers are produced naturally in the rumen of ruminant animals by fermentative bacteria *Butyrovibrio fibrisolvens*, which isomerize linoleic acid into CLA isomers (Fig. 1). A second pathway of CLA synthesis in ruminants is in the mammary gland via δ -9-desaturase of *trans*-11, octadecanoic acid (1). Thus, natural food sources of CLA are dairy products including milk, cheese, butter, yogurt, and ice cream and ruminant meats such as beef, veal, lamb, and goat meat (2–4) (Table 1). The *cis*-9, *trans*-10 (9,11) isomer (i.e., rumenic acid) is the predominating CLA isomer in these products (~80%), whereas the *trans*-10, *cis*-12 (10,12) isomer represents approximately 10%. Although several other isoforms of CLA have been identified, the 9,11 and 10,12 isomers appear to be the most biologically active (5). Levels of CLA isomers in ruminant meats or milk can be augmented by dietary manipulation, including feeding cattle on fresh pasture (6) or by adding oils rich in linoleic acid (e.g., safflower oil) or ingredients that alter biohydrogenation of linoleic acid (e.g., ionophores) to their diet (7).

Figure 1 Structures of linoleic acid, *cis*-9, *trans*-11 CLA, and *trans*-10, *cis*-12 CLA.

Chemical Synthesis of CLA Isomers

Because of the relatively low levels of CLA isomers in naturally occurring foods that are high in fat content, the chemical synthesis of CLA has been developed for making supplements and for fortifying foods. CLA can be synthesized from linoleic acid found in safflower or sunflower oils under alkaline conditions, yielding a CLA mixture containing approximately 40% of the 9,11 isomer and 44% of the 10,12 isomer (reviewed in Ref. 8). Commercial preparations also contain approximately 4% to 10% *trans*-9, *trans*-11 CLA and *trans*-10, *trans*-12 CLA, as well as trace amounts of other isomers.

Table 1 CLA Content of Various Foods

Food	mg/g fat	Food	mg/g fat
Meats/fish		Dairy	
Corned beef	6.6	Condensed milk	7.0
Lamb	5.8	Colby cheese	6.1
Fresh ground beef	4.3	Butter fat	6.1
Salami	4.2	Ricotta	5.6
Beef smoked sausage	3.8	Homogenized milk	5.5
Knackwurst	3.7	Cultured buttermilk	5.4
Smoked ham	2.9	American processed cheese	5.0
Veal	2.7	Mozzarella	4.9
Smoked turkey	2.4	Plain yogurt	4.8
Fresh ground turkey	2.6	Butter	4.7
Chicken	0.9	Sour cream	4.6
Pork	0.6	Cottage cheese	4.5
Egg yolk	0.6	Low fat yogurt	4.4
Salmon	0.3	2% milk	4.1
Vegetable oils		Medium cheddar	4.1
Safflower oil	0.7	Ice cream	3.6
Sunflower oil	0.4	Parmesan	3.0
Peanut	0.2	Frozen yogurt	2.8

PHARMACOKINETICS AND EFFICACY OF CLA

Human and Animal Studies

As with other long chain unsaturated fatty acids (FA)s, CLA is absorbed primarily in the small intestine, packaged into chylomicrons, and distributed to extrahepatic tissues having lipoprotein lipase (LPL) activity or returned to the liver via chylomicron remnants or other lipoproteins. The average daily intake of CLA is approximately 152 to 212 mg for nonvegetarian women and men, respectively (9), and human serum levels range from 10 to 70 $\mu\text{mol/L}$ after supplementation (10,11).

One major discrepancy between animal and human studies is the dose of CLA administered (i.e., equal levels of 9,11 and 10,12 isomers—referred to as a CLA mixture), when expressed per unit body weight. For example, most adult human studies provide 3 to 6 g/day of a CLA mixture, whereas rodent studies provide 0.5% to 1.5% of a CLA mixture (w/w) in the diet. When expressed per unit of body weight, humans receive approximately 0.05 g CLA/kg body weight, whereas mice received 1.07 g CLA/kg body weight, which is 20 times the human dose based on body weight. Thus, part of the discrepancy in results obtained from human and animal studies is likely due to this large difference in the dose of CLA administered. Supplementing humans with higher, or animals with lower, doses of CLA would address this issue. Other discrepancies in experimental designs include using CLA isomer mixtures versus single isomers, duration of CLA supplementation, and the age, weight, gender, and metabolic status of the subjects or animals.

Cell Studies

In vitro studies have been conducted in a variety of cells types, primarily using an equal mixture of 9,11 and 10,12 CLA, or each isomer individually. Doses used in cell studies generally range between 1 to 100 μM , reflecting the concentration found in human participants follow-

ing supplementation. Results from these studies suggest that these isomers are readily taken up by cells. For example, we found that 10,12 CLA is readily incorporated into neutral and phospholipid fractions of the primary human adipocyte cultures and reduced lipid and glucose metabolism (12). Similar to in vivo studies, 9,11 CLA acted more like the linoleic acid controls.

ANTICANCER PROPERTIES OF CLA

CLA Reduces Tumor Growth

Pariza's group initially discovered that CLA isomers in fried ground beef acted as anticarcinogens (13). Subsequently, numerous investigators have shown that CLA mixtures or individual isomers decrease tumor cell growth or increase cancer cell death in in vitro and in vivo models of mammary, gastric, or skin cancer (reviewed in Ref. 14). For example, feeding 0.8% to 1.0% individual CLA isomers or mixtures block the initiation or progression of chemically induced carcinogenesis in several rodent models (15–17). A 5 μM CLA mixture prevented cell growth and cytokine production in transformed human keratinocyte-like cells (18). Proposed anticarcinogenic mechanisms for CLA include decreasing nuclear factor (NF) κB and cyclooxygenase (COX) activity, thereby suppressing the levels of prostaglandin (PG)E₂, an inflammatory PG that promotes the progression of certain forms of cancer and induces human epidermal growth factor receptor 2 (HER2) oncogene expression (19).

CLA Induces Apoptosis of Cancer Cells

Several groups have reported that CLA isomers cause apoptosis or programmed cell death in cancer cells (reviewed in Ref. 11). For example, 32 to 128 μM CLA mixture prevented rat mammary cancer cell growth through apoptosis and decreased DNA synthesis in rat mammary cancer cells (20). Moreover, 40 to 80 μM 10,12 CLA induces apoptosis in breast cancer cells (19,21,22). Proposed proapoptotic mechanisms of CLA include inducing atypical endoplasmic reticulum (ER) stress, leading to caspase-12 activation (22).

In contrast to the cell and animal studies cited in the preceding text, a recent prospective cohort study conducted in Sweden found no evidence to support a protective effect of CLA consumption on the development of breast cancer in women (23). Furthermore, some studies show that 10,12 CLA enhances the risk of developing certain types of cancer (24). Thus, clinical studies examining the effects of purified CLA isomers on preventing or treating cancer, and safety issues, are needed.

ANTIOBESITY ACTIONS OF CLA

Due to the substantial rise in obesity over the past 30 years, there is a great deal of interest in CLA as a weight loss treatment, as it has been shown to decrease body weight and body fat mass (BFM). For example, supplementation with a CLA mixture (i.e., 10,12 + 9,11 isomers in equal concentrations) or the 10,12 isomer alone decreases BFM in many animal and some human studies (reviewed in Refs. 25 and 26). Of the two major isomers of CLA, the

10,12 isomer is responsible for the antiobesity properties (27–31).

CLA Decreases Body Weight and Body Fat Mass

Park et al. (32) were one of the first groups to demonstrate that CLA modulated body composition. Compared with controls, male and female mice supplemented with a 0.5% (w/w) CLA mixture had 57% and 60% less BFM, respectively. Since these findings, researchers have demonstrated that CLA supplementation consistently reduces BFM in mice, rats, and pigs (33–36). For example, dietary supplementation with 1% (w/w) CLA mixture for 28 days decreased body weight and periuterine white adipose tissue (WAT) mass in C57BL/6J mice (36).

In humans, some studies show that CLA decreases BFM and increases lean body mass (LBM), whereas others show no such effects. For example, supplementation of 3 to 4 g/day of a CLA mixture for 24 weeks decreased BFM and increased LBM in overweight and obese people (37). On the other hand, supplementation of 3.76 g/day of a CLA mixture in yogurt for 14 weeks in healthy adults had no effect on body composition (38). Supplementation with 3.2 g/day of a CLA mixture decreased total BFM and trunk fat compared with placebo in overweight participants, but not obese participants (39). These contradictory findings among human studies may be due to the following differences in experimental design: (i) mixed versus individual CLA isomers, (ii) CLA dose and duration of treatment, and (iii) gender, weight, age and metabolic status of the participants.

These antiobesity effects of CLA do not appear to be solely due to reductions in food intake in animals (40–42) or humans (43,44). Several mechanisms by which CLA decreases BFM will now be examined.

CLA Increases LBM

A recent meta-analysis of 18 human, placebo-controlled CLA studies found that consuming a CLA mixture increased fat-free mass (FFM) by 0.3 kg, regardless of the duration or dose (45). When these same 18 studies were examined for reductions in BFM, it was shown that CLA supplementation decreased BFM by 0.05 kg/week for up to one year (25). The average CLA mixture dose for these studies was 3.2 g/day. Collectively, these meta-analyses studies suggest that CLA supplementation of humans results in a rather small but rapid increase in FFM or LBM, and a much larger decrease in BFM over an extended period of time. The effects of CLA on FFM or LBM in humans may vary depending on baseline body mass index, gender, age, and exercise status of the participants.

Two proposed mechanisms by which CLA increases LBM are via increasing bone or muscle mass. 10,12 CLA supplementation for 10 weeks with a 0.5% (w/w) CLA mixture increased bone mineral density (BMD) and muscle mass in C57BL/6 female mice (46). CLA supplementation has been proposed to increase BMD via increasing osteogenic gene expression and decreasing osteoclast activity (46,47). Furthermore, CLA supplementation alone or with exercise increased BMD compared with control mice (48). An alternative mechanism could be that CLA decreases adipogenesis of pluripotent mesenchymal stem cells (MSC) in bone marrow, and instead promotes their

commitment to become bone cells. Indeed, 10,12 CLA has been shown to decrease the differentiation of MSC into adipocytes and increase calcium deposition and markers of osteoblasts (49). In contrast, 9,11 CLA increased adipocyte differentiation and decreased osteoblast differentiation. Consistent with these *in vitro* data, CLA mixture supplementation of rats treated with corticosteroids prevented reductions in LBM, BMD, and bone mineral content (50). Increasing LBM is directly linked to an increase in basal metabolic rate (BMR).

In addition to its effects on BMD, recent evidence supports a role of CLA in increasing endurance and muscle strength. For example, maximum swimming time until fatigue was higher in CLA fed versus control mice (51). Aging mice supplemented with a CLA mixture and 10,12 CLA had higher muscle weight compared with 9,11 CLA and corn oil controls (52). In addition, CLA isomers increased levels of antioxidant enzyme activity, ATP, and enhanced mitochondrial potential, indicating a protective effect against age-associated muscle loss (52). In humans, CLA increased bench-press strength in men supplemented with 5 g/day for seven weeks who underwent resistance training three days per week (53). Furthermore, supplementation with CLA combined with creatine monohydrate (C) and whey protein (P) led to greater increases in bench-press and leg-press strength than supplementation with C+P or P alone (54). Although preliminary, these data suggest that CLA may enhance exercise-induced muscle strength or prevent sarcopenia or age-related muscle loss.

CLA Increases Energy Expenditure

CLA has been proposed to reduce adiposity by elevating energy expenditure via increasing BMR, thermogenesis, or lipid oxidation in animals (27,42,55). In BALB/c male mice fed mixed isomers of CLA for six weeks, body fat was decreased by 50% and was accompanied by increased BMR compared with controls (42). Enhanced thermogenesis may be associated with increased uncoupling of mitochondria via uncoupling protein (UCP)s, which facilitate proton transport over the inner mitochondrial membrane thereby leading to dissipation of energy as heat instead of ATP synthesis. UCP1 is highly expressed in brown adipose tissue (BAT), and in WAT at lower levels. UCP3 is expressed in muscle and in a number of other tissues, whereas UCP2 is the form expressed at the highest level across most tissues. Supplementation with a CLA mixture or 10,12 CLA in rodents induced UCP2 mRNA expression in WAT (29,56). Recently, it was demonstrated that CLA increased mRNA and protein expression of UCP1 in WAT (57). Similarly, CLA supplementation induced UCP gene expression and elevated β -oxidation in muscle and liver (58–62).

CLA Increases Fat Oxidation

CLA has been shown to regulate the gene expression or activity of proteins associated with FA oxidation in adipose tissue, muscle, and liver. For example, CLA induced the expression of carnitine palmitoyl transferase 1 (CPT1) in WAT of obese Zucker *fa/fa* rats (63). Additionally, 10,12 CLA increased the expression of peroxisome proliferator-activated receptor (PPAR) γ coactivator-1 α

(PGC_{1α}) in WAT of mice (57). Consistent with these *in vivo* findings, 10,12 CLA increased β -oxidation in differentiating 3T3-L1 preadipocytes (64). Furthermore, 10,12 CLA treatment increased AMP kinase (AMPK) activity and increased phospho-acetyl-CoA carboxylase (ACC) levels in 3T3-L1 adipocytes, suggesting an increase in FA oxidation and a decrease in FA esterification to triglyceride (TG) (65).

In muscle, 10,12 CLA increased CPT1 expression in hamsters fed an atherogenic diet (60). Supplementation of a CLA mixture in high fat fed hamsters led to increased CPT1 activity in muscle (66). A CLA mixture increased CPT1b, UCP3, acetyl-CoA oxidase (ACO) 2, and PPAR α mRNA levels in skeletal muscle of Zucker rats (67). Consistent with these data, 10,12 CLA increased mRNA levels (63) and activity (68) of CPT1 in the liver. Additionally, 10,12 CLA increased hepatic peroxisomal fatty ACO activity (68), suggesting increased peroxisomal β -oxidation in addition to mitochondrial oxidation. These findings suggest CLA may reduce adiposity through increased energy expenditure via increased mitochondrial uncoupling and FA oxidation in WAT, muscle, and liver.

At least one report demonstrates that CLA increases FA oxidation in human participants (69). In this study, overweight adults supplemented with 4 g/day of a CLA mixture for six months had a lower respiratory quotient (RQ), indicating an increase in FA oxidation compared with placebo controls. However, others have shown no effect of CLA on energy expenditure or fat oxidation in humans (70,71). These discrepancies may be due to the length of treatment, time period of measurement, and time at which measurements are taken. For instance, CLA treatment for four to eight weeks had no effect on energy expenditure or FA oxidation, based on a 20-minute measurement during resting and walking (70). In contrast, the study by Close et al. (69) administered CLA for six months and measured FA oxidation over a 24-hour period and found that CLA increased FA oxidation and energy expenditure. Thus, discrepancies in this area may be due to insufficient duration of CLA treatment or measurements of energy expenditure or FA oxidation.

CLA Decreases Adipocyte Size

Lipolysis is the process by which stored TG is mobilized, releasing free fatty acids (FFAs) and glycerol for use by metabolically active tissues. C57BL/6J mice fed 10,12 CLA for three days had increased mRNA levels of hormone-sensitive lipase (HSL), a key enzyme for TG hydrolysis (56). Consistent with these data, acute treatment with CLA mixture or 10,12 CLA alone increased lipolysis in 3T3-L1 (32,72) and newly differentiated human adipocytes (73). *In vitro*, a CLA mixture and to a greater extent 10,12 CLA decreased TG content, adipocyte size, and lipid locule size in adipocytes (74). Similarly, mice fed 1% CLA displayed increased numbers of small adipocytes with a reduction in the number of large adipocytes (75). Furthermore, a CLA mixture reduced adipocyte size rather than cell number in Sprague Dawley (40) and fa/fa Zucker rats (76). Thus, CLA may reduce adipocyte size by increasing lipolysis.

CLA Decreases Adipocyte Differentiation

The conversion of preadipocytes to adipocytes involves the activation of key transcription factors such as

PPAR γ and CAAT/enhancer-binding proteins (C/EBPs). There is much evidence showing that CLA suppresses preadipocyte differentiation in animal (77–79) and human (12,80) preadipocytes treated with a CLA mixture or 10,12 CLA alone. 10,12 CLA treatment has been reported to decrease the expression of PPAR γ , C/EBP β , sterol regulatory element-binding protein-1c (SREBP-1c), liver X receptor (LXR α), and adipocyte FA-binding protein (aP2), thereby reducing adipogenesis and lipogenesis (12,29,79).

In rodents, supplementation of 10,12 CLA decreased the expression of PPAR γ and its target genes (79,81–83). In contrast, humans supplemented with a CLA mixture had higher mRNA levels of PPAR γ in WAT, but no difference in body weight or BFM (38). In mature, *in vitro*-differentiated primary human adipocytes or in mature 3T3-L1 adipocytes, 10,12 CLA treatment leads to a substantial decrease in the expression and activity of PPAR γ (82,83), and a decrease in PPAR γ target genes and lipid content (80). This shows that 10,12 is not only able to inhibit, but also to reverse the adipogenic process and indicates that this may be mediated by suppression of PPAR γ activity. In addition to its effect on PPAR γ , 10,12 CLA may also directly impact the activity of other transcription factors involved in adipogenesis and lipogenesis (i.e., LXR α , C/EBPs, SREBP-1c), which could contribute to CLA's anti-obesity actions.

CLA Decreases Glucose and FA Uptake and TG Synthesis

Conversion of glucose and FAs to TG is a major function of adipocytes. Genes involved in lipogenesis, such as a LPL, ACC, fatty acid synthase (FAS), and stearoyl-CoA desaturase (SCD), were decreased following supplementation with mixed isomers of CLA or 10,12 CLA alone (12,56,72,80). PPAR γ is a major activator of many lipogenic genes including glycerol-3-phosphate dehydrogenase (GPDH), LPL, and lipin as well as many genes encoding lipid droplet-associated proteins, such as perilipin, adipocyte differentiation-related protein (ADRP), and cell death-inducing DNA fragmentation factor of apoptosis-like effector c (CIDEC) (84). Thus, the antilipogenic action of 10,12 CLA may be explained by inhibition of PPAR γ activity. In addition, CLA repression of expression of SREBP-1 and its target genes may play an important role in delipidation. Finally, CLA suppression of insulin signaling may also impair insulin's ability to activate or increase the abundance of a number of lipogenic proteins including LPL, ACC, FAS, SCD-1, and the insulin-dependent glucose transporter GLUT4.

CLA Decreases Adipocyte Number

Apoptosis is another mechanism by which CLA may reduce BFM. Apoptosis can occur through activation of the death receptor pathway, ER stress, or the mitochondrial pathway. A number of *in vivo* and *in vitro* studies have reported apoptosis in adipocytes supplemented with a CLA mixture or 10,12 CLA alone (56,64,85,86). For example, supplementation of C57BL/6J mice with 1% (w/w) CLA mixture reduced BFM and increased apoptosis in WAT (75). Mice fed a high-fat diet containing 1.5% (w/w) CLA mixture had an increased ratio of BAX, an inducer of apoptosis relative to Bcl2, a suppressor of apoptosis (87).

Figure 2 Reported mechanisms by which 10,12 CLA decreases adipose tissue mass and obesity.

Reported mechanisms by which CLA reduces adiposity are shown in Figure 2.

ANTI-DIABETIC PROPERTIES OF CLA

Feeding obese ob/ob C57BL/6 mice 0.6% 9,11 CLA for six weeks improved plasma levels of glucose, TG, and insulin and reduced the expression of markers of inflammation and insulin resistance in WAT (88). Furthermore, these authors demonstrated that 50 μ M 9,11 CLA prevented tumor necrosis factor (TNF) α -mediated insulin resistance in 3T3-L1 murine adipocytes. Their data suggest that 9,11 CLA improves insulin sensitivity by elevating GLUT4 levels or translocation to the plasma membrane, which are adversely affected by inflammation, thereby facilitating glucose disposal. Similarly, Wistar rats fed a high-fat diet supplemented with a 0.75% to 3.0% CLA mixture for 12 weeks had lower plasma levels of glucose, TG, and insulin compared with high-fat fed control rats (89). The CLA mixture enhanced the expression of PPAR γ target genes in WAT, which was proposed to be responsible for the improvement in insulin sensitivity. Consistent with these data, adiponectin, a WAT-specific, PPAR γ target gene that reduces blood glucose by enhancing its oxidation in liver and muscle, was increased in the plasma of Zucker diabetic fatty (ZDF) rats fed a 1% CLA mixture for eight weeks (55). Similarly, feeding 0.5% 9,11 CLA to insulin resistant C57BL/6J mice improved insulin sensitivity without affecting BFM (90). Conversely, these authors found that feeding 0.5% 10,12 CLA lowered BFM and increased LBM in these mice, but caused insulin resistance. Other studies have also reported that 10,12 CLA causes insulin resistance, especially in mice (81,99). Taken together, these data suggest that 9,11 and 10,12 CLA have opposite effects on insulin sensitivity, most likely due to their opposing effects on the activity of PPAR γ , vis-a-vis 9,11 CLA activates PPAR γ and 10,12 CLA inhibits PPAR γ .

ANTIATHEROSCLEROTIC ACTIONS OF CLA

CLA has been reported to decrease risk factors of atherosclerosis in several important animal models (reviewed in Ref. 91). For example, feeding 0.5% mixed or individual isomers of CLA to New Zealand White rabbits fed a high saturated fat and cholesterol-rich diet reduced blood lipids and atherosclerotic lesion area (92). Syrian Golden hamsters fed a high saturated fat and cholesterol-rich diet containing 1.0% mixed CLA isomers (93), 0.9% 9,11 CLA (94) or 1.0% 10,12 CLA (95), had decreased aortic

lipid accumulation or fewer fatty aortic streaks compared with controls. In apoE $^{-/-}$ deficient mice, feeding a 1.0% CLA mixture decreased aortic lesion area, and reduced macrophage infiltration and inflammatory gene expression in the lesions (96). In contrast to these animal studies, other animal and clinical trials with CLA mixtures have yet to show beneficial effects on reducing risk factors for atherosclerosis (reviewed in Ref. 97).

SAFETY

Adverse side effects have been reported for CLA supplementation such as elevated levels of inflammatory markers, lipodystrophy, steatosis, and insulin resistance. Most adverse side effects are due to the 10,12 CLA isomer.

CLA Increases Markers of Inflammation

Treatment with 10,12 CLA increases the expression or secretion of inflammatory makers such as TNF α , interleukin (IL)-1 β , IL-6, and IL-8 from adipocyte cultures (56,73,80,81,83). Moreover, CLA increases the expression of COX-2, an enzyme involved in the synthesis of PGs, and the secretion of PGF $_{2\alpha}$ (79,98). These inflammatory proteins are known to antagonize PPAR γ activity and insulin sensitivity (87,98–100).

Consistent with these in vitro data, 10,12 CLA supplementation increases the levels of inflammatory cytokines and PGs in humans (101,102). For example, women supplemented with 5.5 g/day of a CLA mixture for 16 weeks had higher levels of C-reactive protein in serum and 8-iso-PGF $_{2\alpha}$ in urine (44). 10,12 CLA supplementation in mice resulted in macrophage recruitment in WAT (81). In contrast, 9,11 CLA exhibits anti-inflammatory actions (6).

CLA Causes Insulin Resistance

Insulin resistance has been reported in vivo (56,102–104) and in vitro (12,73,79,98) following supplementation with a CLA mixture or 10,12 CLA alone. For example, 10,12 CLA supplementation of 3.4 g/day for 12 weeks in obese men with metabolic syndrome increased serum glucose and insulin levels and decreased insulin sensitivity (103). Supplementation with a CLA mixture in type-2 diabetics increased fasting plasma glucose levels and reduced insulin sensitivity (102). Mice fed 1% (w/w) 10,12 CLA displayed elevated fasted and feeding plasma insulin levels and had reduced insulin sensitivity (75). Consistent with these data, the mRNA levels of adiponectin, a key adipokine associated with insulin sensitivity, decrease following supplementation with 10,12 CLA in vivo (36,81,100) and in vitro (79,82,105,106).

CLA Causes Lipodystrophy

The combination of inflammation and insulin resistance results in reduced FA and glucose uptake in WAT, leading to ectopic lipid accumulation in the blood (hyperlipidemia), liver (steatosis), or muscle. CLA-mediated hyperlipidemia and steatosis has been reported in several animal studies (36,76,107). For example, 1% (w/w) CLA time-dependently increased insulin levels and led

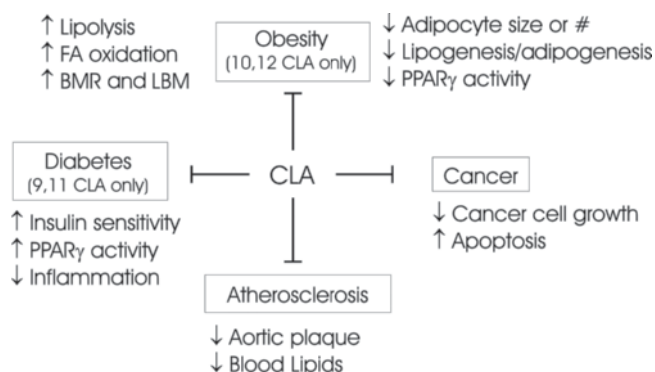

Figure 3 Reported mechanisms by which CLA reduces the risk of cancer, obesity, diabetes, and atherosclerosis.

to increased liver weight and liver lipid accumulation in C57BL/6J mice (36). Aging C57BL/6J mice fed 0.5% 10,12 CLA displayed increased insulin resistance and liver hypertrophy (107).

US Regulatory Status

Recently, the FDA approved CLA as GRAS (generally recognized as safe) for use in foods and beverages (not to exceed 1.5 g/serving) due its potential favorable effects. However, the use of CLA as a dietary supplement or ingredient should be cautioned based on the aforementioned safety issues.

CONCLUSIONS

There is an abundance of evidence in animals suggesting that CLA consumption may reduce the incidence or risk of developing cancer, obesity, diabetes, or atherosclerosis, depending on the type and abundance of CLA isomer consumed and the physiological status of the animal model (Fig. 3). Data on the antiobesity properties of 10,12 CLA in animals, especially mice, are the most reproducible. However, these potential benefits are not without risks, as the 10,12 isomer is associated with increased levels of inflammatory markers, lipodystrophy, and insulin resistance. More clinical studies are needed to determine the efficacy of CLA isomers in humans, and more mechanistic animal and cell studies are needed to determine the precise, isomer-specific mechanisms of action of CLA, and potential side effects.

Copper

Leslie M. Klevay

INTRODUCTION

Since the discovery in 1928 that copper is an essential nutrient, hundreds of experiments to clarify its function have been performed with several species of animals and, under very controlled conditions, with adult human volunteers. People respond to copper depletion similar to animals (1).

The earliest experiments involved hematology, which preoccupied nutritional scientists for decades. Gradually, evidence for the adverse effects of copper deficiency on the cardiovascular and skeletal systems accumulated. Cardiovascular research related to copper deficiency, including associated lipid metabolism and cardiovascular physiology, now exceeds that on hematology. Early work on bone structure and function is being collected and extended.

Methods for assessing nutritional status for copper are poorly developed. However, there are a sufficient number of reports of low activities of enzymes dependent on copper and low copper values in important organs to suggest that a considerable number of people may be too low in this element. These data complement measurements of dietary copper suggesting that the Western diet, which is frequently low in copper, may be the source of this abnormal biochemistry. Some people with abnormal gastrointestinal physiology may absorb too little copper as well.

GENERAL DESCRIPTION

Copper is an essential and versatile nutrient that operates as the active site in 10 to 15 enzymes (1–3). These proteins moderate the chemistry of this metallic element to enhance various metabolic processes related to oxidation. There also are several other copper-binding proteins of physiological importance (3) in addition to some newly discovered proteins called metallochaperones (4). The latter proteins act in the intracellular transport of metallic elements and help to ensure that free copper ion is nonexistent in the body (5,6).

ACTIONS, BIOCHEMISTRY, AND PHYSIOLOGY

The essentiality of copper for mammals, including people, was discovered (7) when rats fed a milk diet with adequate iron became anemic and grew poorly. Copper

proved to be the active material in several foods that were curative and could prevent the condition. All the classic deficiency experiments with animals were performed with milk diets. Adequate copper permits normal utilization of dietary iron. In addition to preventing anemia, it assists in blood coagulation (8,9) and blood pressure control (10,11), crosslinking (2,3,12) of connective tissues of arteries, bones, and heart, defense against oxidative damage (1), energy transformations, myelination of brain and spinal cord, reproduction, and synthesis of hormones (13). Inadequate copper produces adverse effects (14–16) on the metabolism of cholesterol and glucose, on blood pressure control and heart function, on mineralization of bones, and on immunity. Isoprostanes are increased in deficiency (10).

Hypercholesterolemia in copper deficiency has been found in at least 30 independent laboratories (11,17), most recently in studies by Galhardi et al., Kaya et al., and Rosario et al. (18–20) since the original observation (21).

Glutathione is an effective regulator of 3-hydroxy-3-methylglutaryl coenzyme A activity (22,23). Copper deficiency disrupts glutathione metabolism (24), leading to increased activity of this enzyme (25–27) and contributing to the hypercholesterolemia that occurs. In contrast, decreased activities of lecithin: cholesterol acyltransferase (28) and lipoprotein lipase (29) also contribute to the hypercholesterolemia of deficiency.

Electrocardiograms of animals deficient in copper reveal human cardiovascular risk factors such as branch block and abnormalities of the ST segment (15); other heart blocks and wave pathologies are numerous (15). The heart blocks are probably caused by decreased activity of an ATPase isoform localized to the conduction system of the heart (30).

Copper deficiency depresses vasodilation via alterations in nitric oxide physiology (31,32). The mechanism has been reviewed (24,33) and may involve, *inter alia*, guanylate cyclase, which contains copper (34).

Paraoxonase, sometimes called PON1, is a homocysteine thiolactone hydrolase [activity (35) of which is decreased by copper deficiency] (36). The lactone accumulates when homocysteine is elevated and irreversibly inhibits lysyl oxidase (35), which depends on copper for crosslinking of connective tissue in arteries and bone.

There seems to be little doubt that copper deficiency can affect desaturase (and elongase) enzymes, but agreement is lacking on the details and directions of all the changes. Some of the data have been reviewed (14,24,37,38). These enzymes can alter the number of

double bonds in a fatty acid and can also increase its length. Prostaglandin metabolism is also affected (24).

Food Sources and Supplementation

As far as is known, food source does not affect copper absorption, in marked contrast to iron and zinc, which are more easily absorbed from animal, than from plant, products. Higher concentrations of copper in many plant foods can compensate if fractional absorption is slightly lower. Vegetarian diets are high in copper (39,40).

Phytates either have no inhibitory effect on copper, or have a markedly smaller effect than that on zinc (21,41). At intestinal pH, copper complexes with phytates are soluble whereas zinc complexes are not. Phytates can thus enhance the utilization of copper (42).

Copper absorption at 55% to 75% is considerably higher than that of other trace elements; absorption occurs mainly in the upper small intestine, but stomach and colon may absorb the element as well (1). Thus, the concentration of copper in foods is an important characteristic that determines nutritional usefulness. In order of increasing concentration on a weight basis, fats and oils, dairy products, sugar, tuna, and lettuce are low in copper; legumes, mushrooms, chocolate, nuts and seeds, and liver are high in copper (43,44). Bread, potatoes, and tomatoes are consumed in sufficiently large amounts by U.S. adults for these foods to contribute substantially to copper intake, although they are not considered to be high-copper foods (45). Copper and magnesium are highly correlated in U.S. diets (46). Food groups high in folate tend to be high in copper (35).

The Western diet typical of the United States, parts of Europe, and wealthy enclaves in the developing world is often low in copper. Approximately one-third of these diets are low in comparison with those used in successful depletion experiments of men and women (47–51) under controlled conditions and in comparison to the estimated average requirement (EAR) (52) and recommended dietary allowance (RDA) of the National Academy of Sciences (U.S.) (below).

Estimations of dietary copper intakes based on calculations, for example, about Canadian octogenarians (53), from the amount of copper in individual foods are too high according to eight published comparisons (54) to chemical analysis of composite diets; the mean error from calculation is an excess of 77% (54).

The calculated 25th, median, and 75th percentiles for intakes of 51- to 70-year-old men in a statistical sample of the U.S. population (Table C-15 in Ref. 55) are 1.19, 1.47, and 1.81 mg copper daily. Corrections based on the mean excess in copper found by calculation (54) decrease these estimates to 0.67, 0.83, and 1.02 mg daily. Although younger men seem to eat more copper, women eat less!

Data from several publications on dietary intakes of copper based on chemical analyses were pooled (40,44) and a frequency distribution curve was derived for 849 analyzed diets; approximately one-third of the diets contained less than 1 mg of copper daily. Further analytical confirmation of diets low in copper is available from men and women randomly selected in Baltimore. Thirty-six percent and 62% of the diets were below the respective dietary reference intakes for copper (56).

Three approaches to supplementation are available. Diets below the EAR and the RDA can be improved by avoiding foods low in copper and by selecting foods high in copper (43). A copper-deficient salad (lettuce, mayonnaise, oil, tuna, etc.) can be improved by adding sunflower seeds, mushrooms, legumes, etc (44). Soy products are increasingly popular and are high in copper (57), as are nuts (58) and chocolate (59). Beer enhances the utilization of copper in rats fed a deficient diet, resulting in a sixfold increase in longevity, with less cardiac damage and lower plasma cholesterol (60).

In contrast to iron, fortification of foods with copper is uncommon. Some new snacks and drinks promoted as products with exceptional nutritional properties are fortified with copper. A variety of tablets and capsules containing copper are available commercially.

Copper gluconate is the only copper supplement listed by the United States Pharmacopeial Convention and probably is the best supplement for oral use (61). We have used copper sulfate effectively in experiments with animals (21,62) and human volunteers (47,49,51). Others have used copper salts of amino acids (63). Other compounds containing copper, such as the orotate, for which there are no data on bioavailability should not be used. It is not easy to identify the chemical form of copper in some of the available supplements.

Cupric oxide is contained in some vitamin–mineral supplements; this form is no longer used in animal nutrition because the copper is utilized poorly (64). Cupric oxide is used in the preparations with many ingredients because of its high concentration of copper, not because of demonstrated efficacy.

Deficient people should be supplemented with several times the EAR or RDA. Daily supplements of 3 to 7 mg of copper have been tolerated for long periods (65,66).

INDICATIONS AND USAGE

The Western diet is associated with rapid growth in infancy, increasingly early sexual maturation, tall adults, and low rates of infection. This diet is also associated with common diseases of affluence such as cancer, heart disease, obesity, and osteoporosis etc. (67). Numerous anatomical, chemical, and physiological characteristics of people with some of these latter diseases have been found in several species of animals deficient in copper (15,16).

No single indicator provides an adequate assessment of copper nutriture (nutritional status) (52). Indices useful in experiments with animals have sometimes been helpful in depletion studies of people, but most do not seem to be altered by marginal deficiency. Circulating copper may not reflect the actions of enzymes inside cells in various organs where the metabolic processes affected by copper take place. Liver copper, generally impossible to assess in people, is the best indicator in animal experiments (62). Experiments with animals reveal that plasma copper can be normal or increased even though copper in liver or other organs may be low (68–76). Thus, normal or high plasma copper values in people may not be an accurate reflection of copper nutriture.

According to the Oxford Textbook of Medicine (77), low nutrient intakes can reduce nutrient concentrations in tissues and compromise metabolic pathways. Diagnosis then is relatively straightforward upon measurement of the nutrient in suitable tissues or testing of metabolic pathways. Numerous medical publications (some of which are summarized here) reveal low copper concentrations and impaired enzymatic pathways dependent on copper in people. As "nutritional state often alters the expression and course" (77) of illness, extra copper should be provided if low measurements related to copper values are found whether or not they are the cause or the result of the pathology under consideration.

Interpretation of copper or ceruloplasmin in serum or plasma in the assessment of nutriture may be difficult. Low values indicate impairment. Pepys (78) describes the acute phase response to acute and chronic inflammation: a number of plasma proteins, such as ceruloplasmin, are synthesized in liver under the influence of cytokines and are secreted into the circulation. Thus, any illness with a large inflammatory component may have falsely high values (78,79). Normal or high values cannot provide assurance that copper deficiency is not present. Clearly people with myelodysplasia and the new syndrome resembling the neurology of pernicious anemia (below) can be considered for supplementation.

Possibly deficient people should be evaluated with some of the newer, potentially more sensitive, indices of copper status such as erythrocyte and extracellular superoxide dismutases, leukocyte copper, platelet cytochrome c oxidase or serum lysyl oxidase (80–84).

Data on which to base dietary reference intakes for copper are elusive and, often, absent. Consequently, some of the values in Table 1 are rounded and values for males and females are combined. The adequate intake (AI) values are based on intakes of apparently healthy, full-term infants whose sole source of copper was human milk. Values for pregnancy are based on the amount of copper in the fetus and other products of conception. Those for lactation are the amounts needed to replace the average amount secreted in human milk. EARs are values estimated to meet the requirement of half of the healthy individuals of the group. Copper RDAs are based on the EAR plus an assumed coefficient of variation of 15%, which is larger than the 10% assumed for some other nutrients (57).

In the United States, dietary reference intakes are median values with an assumed symmetry of distribution (85). However, there is virtually no information about the

shape of the copper distribution; distributions for most nutrients are skewed to the high end (85). People who are deficient in copper without obvious cause (below) probably have a personal requirement for copper considerably higher than the median requirements reflected in the RDAs.

It seems clear that there is little or no copper deficiency in the industrialized world if one relies on traditional criteria of deficiency such as anemia with decreased plasma copper or ceruloplasmin. However, these markers are affected by the acute phase response and are easily increased by nondietary variables, such as inflammation, oral contraceptives, and pregnancy etc. Copper depletion experiments with men and women reveal unfavorable alterations in biochemistry and physiology with minimal or no changes in circulating copper and without anemia (above). Copper deficiency is the leading nutritional deficiency of agricultural animals worldwide; (86) can people be far behind?

A 2001 report on dietary reference intakes (55) and its predecessors, for example in Ref. (87), summarize the reasons why people may decide to take (or avoid) nutrient supplements. Growth and function are improved when nutrients are increased above levels just sufficient to prevent deficiency. There is little evidence that small surpluses of nutrients are detrimental, while small deficits will lead to deficiency over time. There is no evidence of unique health benefits from the consumption of a large excess of any one nutrient. Meeting recommended intakes for nutrients will not provide for malnourished individuals.

There seems to be little or no anemia responsive to copper in the United States, although this phenomenon does not seem to have been studied adequately in the last six decades. Copper deficiency can masquerade as the myelodysplastic syndrome, however (88–90). Supplementation of middle-aged Europeans with copper protected their red blood cells from oxidative hemolysis *in vitro* (63), indicating that extra copper improved the quality of the cells.

Alzheimer's disease is the leading cause of dementia in the elderly and is of unknown etiology. It is hypothesized that deficiency of dietary copper is the simplest and most general explanation for the etiology and pathophysiology of this disease because, *inter alia*, of numerous reports of low copper in the brain and low activity of enzymes dependent on copper in these patients (91). These findings are consonant with Golden's criteria for diagnosing deficiency (77).

Kumar (92) has reviewed and expanded upon a copper deficiency syndrome resembling the neuropathy of pernicious anemia (vitamin B₁₂ deficiency). Supplementation with cyanocobalamin is useless, but extra copper generally arrests the decline and sometimes reverses some of the signs.

Several of the classical risk factors for ischemic heart disease have been produced in animals deficient in copper. Similar changes have been found in more than 30 men and women in successful copper depletion experiments using conventional foods and have been reversed by copper supplementation (47–51). Copper intakes of 0.65 to 1.02 mg daily in these experiments were insufficient. Criteria of depletion included abnormal electrocardiograms

Table 1 Daily Adequate Intake (AI), Estimated Average Requirement (EAR), and Recommended Dietary Allowance (RDA) for Copper (mg)

Age	AI (mg)	EAR (mg)	RDA (mg)
0–6 mo	0.20 or 30 ($\mu\text{g}/\text{kg}$)		
7–12 mo	0.22 or 24 ($\mu\text{g}/\text{kg}$)		
1–3 yr		0.26	0.34
4–8 yr		0.34	0.44
9–13 yr		0.54	0.70
14–18 yr		0.685	0.89
19–70 yr		0.70	0.90
Pregnancy		0.80	1.00
Lactation		1.00	1.30

(47,48) and blood pressure regulation (51), dyslipidemia (50), glucose intolerance (49), and hypercholesterolemia (47). Two of these experiments were interrupted prematurely with early repletion with copper because of abnormal electrocardiography; all of the metabolic and physiological abnormalities disappeared with copper repletion. Low paraoxonase activity is found in conditions associated with increased risk of ischemic heart disease (36); isoprostanes are increased (93).

In contrast is a balance experiment using a formula diet that failed to confirm these results (94). Applesauce, cheese, chicken, cornflakes, crackers, lettuce, margarine, milk, orange juice, and rice provided less than 31% to 34% of dietary energy (calculated at 2400 kcal/day) (95). As actual energy intake ranged from 2415 to 3553 kcal (94), the food part of the formula was probably about 26%. Because formula diets are known to lower serum cholesterol (96), the potential increase in cholesterolemia from the low copper intake may have been obscured.

Activities of enzymes dependent on copper (97–103) and organ copper concentrations (104–113) have been found to be decreased in people with cardiovascular (mostly ischemic) diseases. There is a positive correlation between cardiac output and copper in heart tissue of patients with coronary heart disease (112). Decreased copper in organs and decreased enzyme activities are evidence of impaired copper nutriture (77,114,115).

No long-term copper supplementation has been performed in patients with cardiac arrhythmia, dyslipidemia, glucose intolerance, hypercholesterolemia, or hypertension. However, some dietary regimens found to alleviate some of these conditions may have included an increase in copper intake as a hidden variable: for example, the Lifestyle Trial (116), the protective effect of legumes on cholesterol, blood pressure, and diabetes (117) and the benefit of whole grain foods on coronary heart disease (118). Spencer (119) described two men and a woman whose premature ventricular beats, which had persisted for years, were thought to be due to coronary heart disease. These premature beats disappeared after they ingested 4 mg of copper (as copper gluconate) per day.

Witte et al. (120) explain how deficiencies of micronutrients, copper among them, can contribute to cardiovascular disease. Patients with heart failure in their supplementation trial had improved ventricular function and quality of life (121); copper in the supplement may have contributed (122). Supplementation trials with vitamins to lower homocysteine may show clinical benefit if extra copper is included (123); copper supplementation (with zinc) improved survival in a long-term, double-blind study of ocular disease (124).

Copper-deficient people have osteoporosis that can be cured with extra copper (reviewed in Ref. 16). This phenomenon has been found mainly in young children. Adults may have skeletal pathology from low copper status as well. Copper is decreased in bone in both osteoarthritis and ischemic necrosis of the femoral head (125). Low serum copper in patients with fractures of the femoral neck (126) or decreased lumbar bone density (14,127,128) may indicate covert copper deficiency. Plasma copper and bone mineral density are correlated (129). Healthy men fed a diet low in copper (0.7 mg/day)

experienced increased bone resorption that returned to normal when copper was replaced (130).

There can be no medical doubt that copper deficiency *can* cause osteoporosis in people. These references on osteoporosis from copper deficiency (131–141) have been found since the earlier review (16) of 17 articles. If copper deficiency turns out to be a major component of the osteoporosis of middle age, supplementation with copper alone is unlikely to be effective. If copper deficiency is corrected, another nutrient, particularly calcium and possibly zinc, may become limiting (77). Two double-blind, placebo-controlled trials have shown that trace element supplements including copper improved bone mineral density in postmenopausal women (65,142).

Premature infants and people with extensive burns may need extra copper. The former (143) are sometimes born before their mothers can load them with copper in the last trimester (12). Premature infants have lower superoxide dismutase activity in erythrocytes and plasma copper after 100 days of life than term infants (144); premature placentas are low in copper and copper-dependent enzymes (145).

In analogy to vitamin B₁₂ deficiency, any disruption of the gastrointestinal tract has the potential to impair copper nutriture. Copper deficiency is being reported with increasing frequency in patients who have had bariatric surgery (90,92,146–149). Some people with cystic fibrosis or pancreatic insufficiency may need extra copper (150–152). Copper-dependent enzyme activity and copper concentration have been found to be decreased in ulcerative colitis biopsies (153). Supplementation of people with these conditions should be performed under medical supervision.

If adults have unmet needs for copper to provide cardiovascular, hematopoietic, or skeletal benefit, neither the dose nor the duration of therapy is clear. A potential role for copper supplements in the treatment of rheumatoid arthritis and psoriasis has not been proved. There is probably no reason to exceed the tolerable upper intake level (UL) of 10 mg daily (Table 2).

Potential Toxicity and Precautions

All chemicals, including essential nutrients, are toxic if the dose is excessive. It seems that people have a 50- to 400-fold safety factor for copper considering usual dietary intakes and the tolerance level found with several species of experimental animals (154). The UL connotes an intake

Table 2 Daily Tolerable Upper Intake Level (UL) for Copper (mg)

Age group	UL (mg)
Children	
1–3 yr	1.00
4–8 yr	3.00
9–13 yr	5.00
Adolescents	
14–18 yr	8.00
Adults	
19–70+ yr	10
Pregnancy	8.00
Lactation	8.00–10.00

that can, with high probability, be tolerated biologically by almost all individuals.

Gastrointestinal signs and symptoms such as nausea are prominent in the setting of this limit. A small, double-blind study has revealed that adults are unaffected in 12 weeks by a daily supplement of 10 mg of copper (52). The UL values in Table 2 are based on this experiment; no value is available for infants less than 1-year-old. van Ravesteyn (155) administered 38 mg of copper daily to people for as long as 14 days; toxicity was not mentioned. Copper supplements should be taken with food (156,157) and should not be taken by people with biliary disease, liver disease, idiopathic copper toxicosis or Wilson's disease, or by people taking penicillamine or trientine.

Although copper can interfere with zinc utilization, this phenomenon does not seem to be of practical importance to people. In contrast, copper deficiency has been induced in people (and in numerous species of pets and animals in zoos) by the ingestion of recently minted pennies (United States), which are almost pure zinc (158). The dose of supplemental zinc that is excessive for adults is ill-defined, but the adult UL for zinc, 40 mg daily, is based on reduced copper nutrition from zinc in food, water, and supplements combined. A case of copper-responsive anemia has been reported in a patient with acrodermatitis enteropathica overtreated with zinc (159). This potential exists for patients with Wilson's disease treated with zinc, particularly children (160). Demyelination of the central nervous system has been reported from overzealous treatment of Wilson's disease with zinc (161). Denture creams high in zinc have led to copper deficiency (162,163).

Vitamin C is known to interfere with the utilization of copper (131,164–168), but its UL of 2 g daily is not based on copper effects. Adverse effects on blood pressure regulation and copper utilization were found in women fed 1.5 g vitamin C daily (51). Simple sugars such as fructose, glucose, and sucrose interfere with the utilization of copper (169,170): High-fructose corn syrup is found in many processed foods and beverages. Excessive ingestion of soft drinks (171,172) has contributed to copper deficiency. High iron intakes can disrupt copper utilization (85,131,173–175). People with iron overload (176,177) and lead poisoning (178–180) may benefit from copper supplementation. Copper supplements should not be used as emetics.

CONCLUSIONS

The Western diet often is low in copper. Statements to the contrary are based on dietary calculations, which are falsely high. The best way to ensure an AI of copper is to minimize the intake of foods low in copper and to increase that of foods high in it, such as cereals, grains, legumes, mushrooms, nuts, and seeds. Dietary copper can be increased by using the food pyramid as a guide. Only a few foods are fortified with copper. Copper gluconate is probably the best supplement.

There seems to be little copper deficiency in Western society if one considers anemia as its only sign. However,

adults with diseases of the cardiovascular, gastrointestinal, and skeletal systems have repeatedly been found to have low concentrations of copper in important organs and to have low activities of enzymes dependent on copper. These signs are consonant with deficiency. Premature infants may also be deficient in copper. Large intakes of vitamin C or zinc can impair the proper utilization of copper in people.

People deficient in copper are being reported with increasing frequency. Although many circumstances seem without explanation and because the clinical signs differ from those traditionally associated with copper deficiency, the reports are often scattered in medical journals that do not have the word "nutrition" in their titles.

Recognition of copper deficiency in the general population still seems rare enough to be published, but deficiency also is common enough that 10 cases are reported from one neurological clinic. The index of suspicion should be increased among those providing primary care. When obvious explanations such as bariatric surgery, dental adhesives high in zinc, hemochromatosis, lead poisoning, and soft drink excess are excluded one should consider the possibility that the patient has a dietary requirement higher than those mentioned among the dietary reference intakes. Some cases of myelodysplastic syndrome and heart failure respond to copper.

Evaluations should not rely only on plasma copper or ceruloplasmin. Supplementation should be done with substantial doses of easily absorbed, copper salts under medical supervision.

Some successful experiments in human copper depletion, particularly in relation to the cardiovascular system, are summarized here, as are some unsuccessful experiments. Others have been reviewed (181). Depletion experiments with positive results illustrate what is possible in the wider world, particularly when the potentially adverse effects were eliminated on repletion. Seemingly contrary or incongruous experiments should not promote denial or negativism; rather they should stimulate searches for explanations of differences.

Individual animals and individual people fed the same depleted diets do not respond uniformly. Signs of deficiency are variable in experimental pellagra and in animal experiments on biotin, thiamin, or copper deficiencies. Our success rate in inducing copper depletion in people resembles that of Goldberger in inducing pellagra. One should not expect all people to respond uniformly to a diet low in copper (15).

There is no information available on how copper requirements vary from person to person; dietary recommendations are based on assumptions of narrow variability. The amount of copper in the body and its variability are known, only inaccurately. Copper absorption is reasonably well defined, but data on copper losses are scant. Aside from some obvious causes of deficiency mentioned here, causes of human deficiency in some recent, medical reports are unknown. These reports have increased since the first edition and illustrate opportunities for research; it seems likely that people with unidentified high requirements for copper are eating too little. The field of copper nutrition is far from stagnant.

Cordyceps

John Holliday, Matt Cleaver, Mojca Tajnik, Joseph M. Cerecedes, and Solomon P. Wasser

ABBREVIATIONS

ATP, adenosine triphosphate; GM-CSF, granulocyte macrophage colony-stimulating factor; GRAS, generally recognized as safe; HDL, high-density lipoprotein; IFN, interferon; Ig, immunoglobulin; IL, interleukin; iNOS, calcium-insensitive nitric oxide synthases; LD₅₀, median lethal dose; LDL, low-density lipoprotein; NK cell, natural killer cell; PAH, polyaromatic hydrocarbons; PAMP, pathogen-associated molecular patterns; TCM, traditional Chinese medicine; TLR, Toll-like receptor; TNF, tumor necrosis factor.

INTRODUCTION

Species of the genus *Cordyceps* (Fr.) Link (also known as Chinese caterpillar fungi, or Tochucaso in Japanese; Clavicipitaceae, Ascomycetes) are the fungi found growing on insect larvae (Fig. 1), mature insects, or fruiting bodies of truffles of genus *Elaphomyces*. *Cordyceps* has a long history as a rare and exotic medicinal fungus. It has been a highly regarded cornerstone of Chinese medicine for centuries; one that reportedly has a number of far reaching medicinal effects (1). Most people in the West have only come to know of *Cordyceps* within the last twenty years, during which time, modern scientific methods have been increasingly applied to the investigation of its seemingly copious range of medicinal applications, in an attempt to validate what Chinese practitioners have noted for centuries (2).

BACKGROUND

Diversity and Artificial Cultivation

There are currently more than 680 documented species of *Cordyceps*, found on all six inhabited continents and in many climatic zones and habitats, and occurring parasitically or commensally with a range of hosts (2–3). Due to the rarity and high prices of the wild collected variety, attempts have long been made to cultivate *C. sinensis*. By the mid 1980s, the majority of *C. sinensis* available in the world's marketplace was artificially cultivated (4).

Many companies now produce artificially cultivated *C. sinensis* products, both from the mycelium as well as from the fruit bodies. The increase in supply has given rise to variations in purity and quality, creating a situation in which there are a large number of counterfeit and adulterated products being sold (3). Recently, there have been introduced, new methods for assaying the quality of *Cordyceps* spp. products (5). The large variations in quality

found in cultivated *C. sinensis* has lead many consumers to believe the wild collected variety is medicinally better than the cultivated type. But with new advances in biotechnology, this is rapidly changing (6).

Contamination and Adulteration of *Cordyceps*

As found in its natural state, *C. sinensis* is attached to the mummified body of the caterpillar, from which it arose. It is harvested whole in this way, dried, and supplied into the market. Because *C. sinensis* is sold by weight and intact fruiting bodies fetch higher prices in traditional markets, collectors have historically inserted a small bit of twig into many of the caterpillars, resulting in an increase in weight and the appearance of intact fruiting bodies (5). This is probably a harmless practice, as long as the object inserted is from a nontoxic source. However, modern collectors have inserted lead or other metal in order to boost the weight, so anyone who chooses to use the wild collected *C. sinensis*, rather than the cultivated variety, would be well advised to break each one of the caterpillars in half before use, so that any bits of foreign matter can be readily discerned and removed.

History and Traditional Uses

The first written record of the *Cordyceps* mushroom comes from China, in the year AD 620, at the time of the Tang Dynasty, bringing substance to the once intangible allegorical narrative, which spoke of a creature, whose annual existence alluded to a transformation from animal to plant, in summer, and then again from plant to animal, in winter (1). Tibetan scholars wrote of the healing animal/plant through the 15th to 18th centuries, and in 1757, the earliest objective and scientifically reliable depiction of the *Cordyceps* mushroom was written by the author Wu-Yiluo in the Ben Cao Congxin ("*New Compilation of Materia Medica*"), during the Qing Dynasty (2–3).

C. sinensis is found at high altitudes on the Himalayan Plateau, and thus, is difficult to harvest. Due to such difficulties, *Cordyceps* has always been one of the most expensive medicinal fungi known. Its high price had relegated it almost exclusively to members of the Emperor's court and others among the Chinese nobility, historically beyond the reach of the average Chinese subject. Despite its cost and rarity, the unprecedented litany of medicinal possibilities for *Cordyceps* spp. has made it a highly valued staple of the TCM.

The name *Cordyceps* comes from the Latin words, *cord* and *ceps*, respectively meaning, "club" and "head." The Latin word conjunction accurately describes the appearance of these club fungi, whose stroma and fruit body

Figure 1 *Cordyceps sinensis* in natural habitat (4550 m in Tibet, China).

extend from the mummified carcasses of insect larvae, usually that of the Himalayan ghost Moth, *Thitarodes armoricanus* (*Hepialis armoricanus*). In historical and general usage, the term "*Cordyceps*" normally refers specifically to the species *C. sinensis*. However, the name "*Cordyceps*" has come to be used for a number of closely related species over the last few years, which have been found to be much easier to cultivate. While *C. sinensis* may be the most well-known species, there are many other species in the genus *Cordyceps*, in which modern science may have uncovered potentially valuable medicinal properties.

The medicinal values of *Cordyceps* spp. have been recognized since ancient times in China and the surrounding Orient; but knowledge of this only reached Western scientific audiences in 1726, when it was introduced at a scientific meeting in Paris. The first specimens were carried back to France by a Jesuit priest, who chronicled his experiences with the *Cordyceps* mushroom during his stay at the Chinese Emperor's court (1,4).

The range of therapeutic uses claimed for *Cordyceps* spp. is far reaching; although most of them have yet to be sufficiently investigated. In TCM, *C. sinensis* has been used to treat conditions including respiration and pulmonary diseases, renal, liver, and cardiovascular diseases, hyposexuality, and hyperlipidemia. It is also used in the treatment of immune disorders and as an adjunct to modern cancer therapies (chemotherapy, radiation treatment, and surgery) (1). *C. sinensis* is believed by many, particularly in and around Tibet, its place of origin, to be a remedy for weakness and fatigue; and it is often used as an overall rejuvenator for increased energy while recov-

ering from a serious illness. Many also believe it to be a treatment for impotence, acting as an aphrodisiac in both men and women. *C. sinensis* is often prescribed for the elderly to ease general aches and pains. TCM practitioners also recommend the regular use of *C. sinensis* in order to strengthen the body's resistance to infections, such as colds and flu, and to generally improve the homeostasis of the patient.

CHEMISTRY AND PREPARATION OF PRODUCTS

Nutritional Components

Cordyceps spp. contains a broad range of compounds, which are considered nutritional. *C. sinensis* contains all of the essential 18 amino acids. The content of amino acids after hydrolysis is mostly reported in the range of 20% to 25%. The highest contents are glutamate, arginine, and aspartic acid, and the major pharmacological components are arginine, glutamate, tryptophan, and tyrosine (7). Also found are vitamins E, K, and the water-soluble vitamins B1, B2, and B12. In addition, *Cordyceps* spp. contain many sugars, including mono-, di-, and oligosaccharides, and many complex polysaccharides, proteins, sterols, nucleosides, macro- and microelements (K, Na, Ca, Mg, Fe, Cu, Mn, Zn, Pi, Se, Al, Si, Ni, Sr, Ti, Cr, Ga, V, and Zr) (2,5).

Polysaccharides

C. sinensis contains a large amount of polysaccharides, which can be in the range of 3% to 8% of the total weight, and usually comes from the fruiting bodies, the mycelium of solid fermentation submerged cultures and the broth (7). Four β -D-glucan exopolysaccharides from *C. militaris* with different molecular masses ranging from 50 to 2260 kDa were reported by Kim et al. (8). In the case of *C. sinensis*, most of the heteropolysaccharides contained mannose, galactose, glucose, and mannose in higher levels with smaller amounts of arabinose, rhamnose, fructose, and xylose, respectively. The average molecular mass varies between 7 and 200 kDa. *C. militaris* polysaccharides consisted mostly of glucose, galactose, and mannose with traces of rhamnose and xylose and average molecular weight approximately 60 kDa (9).

Proteins and Nitrogenous Compounds

Cordyceps spp. contain proteins, peptides, polyamines, all essential amino acids, some uncommon cyclic dipeptides, including cyclo-[Gly-Pro], cyclo-[Leu-Pro], cyclo-[Val-Pro], cyclo-[Ala-Leu], cyclo-[Ala-Val], and cyclo-[Thr-Leu]. Small amounts of polyamines, such as 1,3-diamino propane, cadaverine, spermidine, spermine, and putrescine, have also been identified (4). Many nucleosides have been found in *Cordyceps* spp., including uridine, several unique deoxyuridines, adenosine, dideoxyadenosine, hydroxyethyladenosine, cordycepin [3'-deoxyadenosine], cordycepin triphosphate, guanidine, deoxyguanidine, and other altered and deoxygenated nucleosides, many of which are found nowhere else in nature (Fig. 2). Chen and Chu (10) found cordycepin and 2'-deoxyadenosine in an extract of *C. sinensis*.

Sugar-binding proteins named lectins were isolated from *C. militaris*. N-terminal amino acid sequence differed

Figure 2 Some of the unique nucleosides found in *C. sinensis*.

greatly from other lectins (11). Production of the nonribosomal peptides cicapeptins I and II from *C. heteropoda* were reported by Krasnoff et al. (12).

Sterols

A number of sterol-type compounds have been found in *Cordyceps* spp.: ergosterol, δ -3 ergosterol, ergosterol peroxide, 3-sitosterol, daucosterol, and campesterol, to name a few (1). Another compound, sterol H1-A was found by Chen et al. (13) and it was claimed to be effective in the treatment of autoimmune disorders.

Other Constituents

Twenty-eight saturated and unsaturated fatty acids with the function of decreasing blood lipids and protecting against cardiovascular disease, and their derivatives, have been isolated from *C. sinensis*. The unsaturated fatty acid content includes C16:1, C17:1, C18:1, and C18:2 (7).

Polar compounds of *C. sinensis* extracts include many alcohols and aldehydes (1). Particularly interesting is the range of polycyclic aromatic hydrocarbons produced by many *C. sinensis* strains, named PAH compounds, for which it was proposed to react with the polypropylene used in common mushroom culture bags, resulting in the production of byproducts toxic to *C. sinensis* and stunting growth as time progresses (5). Of particular note are various immunosuppressive compounds found in *Cordyceps* spp., including cyclosporin from *C. subsessilis* (anamorph: *Tolypocladium inflatum*) (14), and also compounds found in *Isaria sinclairii*, a species closely related to the genus of *Cordyceps* (3).

Preparation of Products

Various pure compounds, extracts, whole fungus, and other preparations have been used in preclinical and clinical studies, and several products are now available in the market, mostly used as food supplements. In TCM, hot-water extraction of whole fruiting bodies is traditionally used. Nowadays, extracts of polysaccharides are mainly obtained by hotwater extraction followed by ethanol precipitation (15). For pure compounds, different types of chromatography are used, mainly affinity, ion-exchange or size-exclusion chromatography. It should be noted that different types of extracts give different results in the studies mentioned, but all of them show positive medicinal value.

PRECLINICAL STUDIES

The widespread use of *Cordyceps* spp. in TCM has been discussed above in the section on History and Traditional Uses. One of the most significant proposed activities of medicinal mushrooms is their role as immunomodulators. Other activities ascribed to *Cordyceps* spp. are anti-tumor, antimetastatic, immunomodulatory, anti-oxidant, anti-inflammatory, insecticidal, antimicrobial, hypolipidaemic, hypoglycemic, anti-aging, neuroprotective and renoprotective activities (2).

Cancer

A possibly valuable therapeutic application of *Cordyceps* spp. is its potential as a treatment for cancer, and as an adjunct to chemotherapy, radiation, and other conventional and traditional cancer treatments (2,4). The mechanism by which *Cordyceps* inhibits the growth of various cancer cells might occur by one of several means: by enhancing immunological function and nonspecific immunity; by selectively inhibiting RNA synthesis, thereby affecting the protein synthesis; by restricting the sprouting of blood vessels (angiogenesis); by inducing tumor cell apoptosis; by regulation of signal pathways; anti-oxidation and anti-free radical activity; anti-mutation effect; interfering with the replication of tumor-inducing viruses; and by inducing nucleic methylation (7).

Growth inhibition of various cancer cells by enhancing immunological function and nonspecific immunity is usually linked to polysaccharides, especially β -D-glucans, which present major cell wall structural components in fungi and are also found in plants and some bacteria but not in animals. Consequently, they are considered to be classic pathogen-associated molecular patterns, called as PAMPs (16). PAMPs potently trigger inflammatory responses in a host, as if it was infected by a fungus. Studies have shown that β -D-glucans initiate biological response with binding to complement receptor 3 (CR3) located on the surface of the immune system effector cells, like macrophages, thereby setting up different intercellular activities of the immune system and leading to production of cytokines, such as TNF- α , interleukins, interferons, and finally apoptosis of tumor cells (17). Toll-like receptors (especially TLR-2) and dectin-1 receptor play an important role in internalization and signaling responses to fungal β -D-glucans (18).

The anti-tumor effect also has been related to the inhibition of DNA and RNA synthesis (19). Studies (20) have demonstrated that cordycepin can selectively inhibit mRNA synthesis, which affects protein synthesis by competing with adenosine nucleoside phosphatase. The inhibition may be blocked by adenosine. Cordycepin can also kill leukemia cells and extend the period of mitotic cells in the S and G phases. Nakamura et al. (21) found that, with respect to cancer cells and normal cells, cordycepin caused an inhibition rate of cell division on cancer cells of 55% while only 1.5% on normal cells. These results show that cordycepin may have a very slight effect on the human body while treating cancer.

Another mechanism is inducing tumor cell apoptosis. Extracts of *C. militaris* inhibited cell growth of human leukemia cells in a dose-dependent manner (22), which was associated with morphological change and apoptotic cell death, such as formation of apoptotic bodies and DNA fragmentation. Results indicated that the antiproliferative effects were associated with the induction of apoptotic cell death through regulation of several major growth regulatory gene products (23).

In cancer research, there have been many studies made with *Cordyceps* spp. extracts using animal models. *C. militaris* inhibited the growth and metastasis of Lewis lung cancer cells and the growth of sarcoma S180 cells implanted in mice. In addition, the survival period of the mice was increased (24). A study using murine models verified that oral administration of a hot water extract of *C. sinensis* consequently resulted in the activation of macrophages, thereby increasing the production of GM-CSF and IL-6, which act on the systemic immune system (25). In another study (26), mice treated with cyclophosphamide, which suppresses immune function, and with *C. sinensis* hot water extract saw their immune function return to normal, as measured by the IgM and IgG response and macrophage activity.

Fatigue

Trials in the mouse swim test, conducted using *C. sinensis* added to a standard diet compared with use of the untreated standard diet, have invariably shown the use of *C. sinensis* to significantly increase the time to exhaustion in laboratory animals over their control groups (4). The use of *C. sinensis* by athletes stems from publicity surrounding the performance exhibited by the Chinese Women's Track and Field team at the Chinese National games in 1993. In this competition, nine world records were broken by substantial margins. The team's coach attributed their success to *C. sinensis* (27). An increase in cellular ATP level results in an increase in useful energy, in contrast to the perceived increase in energy, which occurs from the use of other stimulants, such as caffeine, ephedrine, and amphetamines, ultimately resulting in an energy deficiency (28).

Hypoglycemic Effects

In animal studies, isolated polysaccharides, have been shown to improve blood glucose metabolism and increase insulin sensitivity in normal animals, to lower blood sugar levels in genetically diabetic animals, and to positively effect blood sugar metabolism in animals with chemically

induced diabetes (29–31). The common thread throughout all these trials is the increase in insulin sensitivity and hepatic glucose-regulating enzymes, glucokinase and hexokinase.

Lung Ailments

Mice treated with *C. sinensis* were able to survive up to three times longer than those left untreated, demonstrating a more efficient utilization of the available oxygen. Such efficacy alludes to the use of *C. sinensis* as an effective treatment for bronchitis, asthma, and chronic obstructive pulmonary disease (32). A study was conducted using in vivo mouse model-induced acute pulmonary edema, which causes systemic lack of oxygen, acidic body, and death. Research results show that animals taking *C. sinensis* had a significantly greater survival rate of 20% mortality in comparison with 80% mortality of the control group (33).

Male/Female Sexual Dysfunction

C. sinensis has been used for centuries in TCM to treat male and female sexual dysfunction, such as hypolibidism and impotence. Preclinical data on the effects of *C. sinensis* on mice showed sex steroid-like effects (4), and human clinical trials have demonstrated similarly the effectiveness of *C. sinensis* in combating decreased sex drive and virility (34). Treatment of rats on a diet supplemented with *C. militaris* mycelium resulted in an increase of serum cordycepin concentration, serum testosterone, and serum estradiol-17 concentrations. They proposed that supplementation with *C. militaris* improves sperm quality and quantity in rats (35).

Antiviral Activity

The recognition of bacteria, viruses, fungi, and other microbes is controlled by host immune cells with many innate immunity receptors, such as Toll-like receptors, C-type lectin receptors, and immunoglobulin-like receptors. Studies indicate that the immune modulating properties of *C. sinensis* could be attributed to their polysaccharide components. These polysaccharides specifically interact with and activate surface receptors involved in innate immunity (36). It was shown that intranasal administration of an acidic polysaccharide, isolated from the extract of *C. militaris* grown on germinated soybeans, decreased virus titers in the bronchoalveolar lavage fluid and the lungs of mice infected with influenza A virus. Furthermore, it increased TNF- α , IFN- γ , IL-1, IL-6 and IL-10 levels, enhanced nitric oxide production, and induced iNOS mRNA expressions in murine macrophage cells (37).

CLINICAL STUDIES

Due to the historically high cost of the fungus and the only recently developed methods for artificial cultivation, clinical trials of *C. sinensis* and its extracts are still relatively new endeavors. Earlier trials, although few in number, have set the precedent from which modern trials are building, expanding, and cementing our understanding of *Cordyceps* spp. The majority of clinical trials mentioned in this section used standard double-blind placebo-controlled protocols. Approval was granted in the

countries where the trials were performed, but in most cases the trials were conducted in China.

Cancer

The belief in the efficacy of *C. sinensis* against cancer is widespread in the Orient, and many cancer patients in Japan, Korea, and China are taking *C. sinensis*, or some other mushroom-derived immunomodulators [such as PSK™, PSP™, Lentinan™, AHCC™, Immune Assist™ (a heteropolysaccharide complex formula), and arabinoxylnes (MGN3™)], while undergoing conventional treatment (1). Clinical studies involving cancer patients have been conducted mostly in China and Japan (38,39). In one study of 50 patients with lung cancer, who were administered *C. sinensis* at 6 g/day, in conjunction with chemotherapy, tumors were reduced in size in 46% of the patients studied. A trial involving cancer patients with several different types of tumors found that *C. sinensis*, taken over a two-month period at 6 g/day, improved subjective symptoms in the majority of patients. White blood cell counts were kept at 3000/μL, or higher; and even with radiation or chemotherapy, other immunological parameters showed no significant change, while tumor size was significantly reduced, indicating an improved tolerance for radiation and/or chemotherapy (1). In addition, natural *C. sinensis* has been shown to enhance the NK cell activity of normal patients by 74% and increased the NK activity of leukemia patients by 400% (39).

Fatigue

In a placebo-controlled clinical study of elderly patients with chronic fatigue, results indicated that most of the participants treated with *C. sinensis* reported a significant clinical improvement in the areas of fatigue, cold intolerance, dizziness, frequent nocturia, tinnitus, hyposexuality, and amnesia, while no improvement was reported in the placebo group (4,40–42). Another study involving healthy elderly volunteers, with an average age of 65, tested the output performance and oxygen capacity of participants while exercising on stationary bicycles. A portion of the volunteers consumed *C. sinensis* for six weeks, while others consumed a placebo. The results demonstrated that the *C. sinensis* group had a significant increase in energy output and oxygen capacity over the placebo group after six weeks of the study (43). The presence of adenosine, cordycepin, D-mannitol, polysaccharides, vitamins, and trace elements may be, at least partially, the cause for such effects.

Kidney Ailments

Traditional views of the *Cordyceps* spp. held that its consumption strengthened the kidneys. In a study of 51 patients suffering from chronic renal failure, it was found that *C. sinensis* significantly improved both the kidney function and overall immune function of treated patients, compared with the untreated control group (44). Patients with chronic renal failure or reduced kidney function often suffer from hypertension, proteinuria, and anemia. After a one-month treatment with *C. sinensis*, patients showed a 15% reduction in blood pressure, reduction in urinary protein, and increases in superoxide dismutase (44). Fifty-one percent improvement of chronic kidney diseases was

shown only one month after taking *C. sinensis* supplement (45). In another clinical study, treatment with *C. sinensis* of patients having gentamicin-induced kidney damage resulted in the recovery of 89% of their normal kidney function after six days, compared with only 45% recovery by patients treated with more conventional methods (1).

Hypoglycemic Effects

In a randomized trial, 95% of patients treated with *C. sinensis* showed improvement in their blood sugar profiles, while the control group showed only 54% improvement with treatment by other methods (46).

Lung Ailments

There have been many trials in humans, using *Cordyceps* spp. to treat many respiratory illnesses, including asthma and bronchitis, either alone or as an adjunct to standard antibiotic therapy, and it appears to be useful for all of these conditions (47–50). Extracts of *C. sinensis* have been shown to inhibit tracheal contractions, especially important in asthma patients, since it allows for increased airflow to the lungs. In addition, its anti-inflammatory properties may prove to bring further relief to asthma patients, whose airways become obstructed, due to an allergic reaction resulting in the swelling of the bronchial pathways (1). In a double-blind placebo-controlled study with 30 elderly volunteers, *C. sinensis* significantly improved the maximum amount of oxygen these people were able to assimilate (51).

Heart Ailments

It has been shown that *C. sinensis*, which often has a significant quantity of adenosine, along with adenosine-type nucleotides and nucleosides, has an effect on coronary and cerebral circulation (52,53). In studies of patients suffering from chronic heart failure, the long-term administration of *C. sinensis*, in conjunction with conventional treatments, promoted an increase in the overall quality of life (42). This included general physical condition, mental health, sexual drive, and cardiac function, compared with the control group. Studies have also shown the benefits of *C. sinensis* on heart rhythm disturbances, such as cardiac arrhythmias and chronic heart failure (54).

Liver Ailments

In the Orient today, *C. sinensis* is commonly used as an adjunct in the treatment of chronic hepatitis B and C. In one study, *C. sinensis* extract was used in combination with several other medicinal mushroom extracts as an adjunct to lamivudine, for the treatment of hepatitis B. The group receiving *C. sinensis* along with other medicinal mushroom extracts had much better results in a shorter period of time than the control group, who received only lamivudine (55). Treatment of 22 patients, diagnosed with posthepatic cirrhosis, with *C. sinensis* (56), showed improvement in liver function tests, and in another trial on patients with hepatitis B and patients with cirrhosis taking *C. sinensis* supplement showed around 80% improvement of liver functions (57).

Hypercholesterolemia

In both human and animal studies, administration of *C. sinensis* has been associated with cholesterol and triglyceride reduction and an increase in the ratio of HDL to LDL cholesterol (1). As such it may prevent, arrest, and even reverse coronary atherosclerosis (58). The studies have demonstrated that *C. sinensis* helps to lower total cholesterol up to 21% and triglycerides up to 26%. At the same time it helps to increase HDL cholesterol up to 30% (54).

Antiviral Activity

After three months of treatment of chronic hepatitis B patients using *C. sinensis*, CD4 and CD4/CD8 ratios increased significantly (59). The results suggest that beneficial effects might be obtained through adjustment of the T lymphocyte subsets level. Treatment of 65 cases (with 20 cases in the control group) of patients with posthepatic cirrhosis has shown similar results (60). Extracts of *Cordyceps* spp. are also effective against HIV infections. A *C. sinensis* containing formula named Immune Assist 24/7™ has recently been introduced throughout West Africa for use in treating HIV infections and other immune-deficient states (2), and is quite popular with both the doctors and the patients due to its low toxicity and cost when compared with other antiretroviral drug options.

Dosage

Because clinical data on *Cordyceps* spp. is relatively new, and even more so in Western Countries, recommended dosage requirements may vary, depending on the source. In general, clinical trials have been conducted using 3 to 4.5 g of *C. sinensis* per day, except in cases of severe liver disease, where the dosage has usually been higher, in the range of 6 to 9 g per day (4). There are some practitioners known to these authors, who keep their cancer patients on 30 to 50 g of *C. sinensis* per day. While this may seem excessive, the clinical results seen with this treatment regimen are promising, and *Cordyceps* spp. related toxicity has never been reported.

C. sinensis has been traditionally taken in tea or eaten whole, either by itself or cooked with a variety of meats. Today, in addition to the established traditional means of consumption, powdered mycelium and mycelial extracts are also available in capsulated and noncapsulated form. At present, there are no reliable standards by which to compare different brands, but in general, the quality of *Cordyceps* spp. is improving, as methods of more efficient cultivation are investigated; and as more clinical trials are conducted, a clearer picture of recommended dosages for a particular condition will become more standardized. Considering the quality of cultivated *Cordyceps* spp. available in the market today and the risk of lead exposure as well as the cost, such as with wild *C. sinensis*, the use of natural *Cordyceps* spp., over the artificially cultivated variety, is not recommended. Obtaining *Cordyceps* spp. from a reliable source, with complete analytical data provided, is the safest way to purchase species of *Cordyceps*.

Safety Profile

None known contraindications.

Drug Interactions

There is observational evidence that the alteration of the body's blood glucose metabolism in patients consuming *Cordyceps* spp. often results in the reduction of oral or injected anti-diabetic medications. It is also posited that the naturally occurring antiretroviral compounds found in *C. sinensis* (e.g., 2,3-dideoxyadenosine) are marketed as a major anti-HIV drug under the name Videx and Didanosine, as well as 3-deoxyadenosine (which has the same or at least similar activity); *C. sinensis* could result in increased effectiveness or decreased dosage requirements for patients undergoing concurrent therapy with other antiretroviral drugs. Caution should be exercised in these patients, especially considering the newer, more potent hybrid strains of *Cordyceps* spp. being developed, and the targeted medicinal compounds being selectively cultivated.

Adverse Side Effects

Very few toxic side effects have been demonstrated with *Cordyceps* spp. use, although a very small number of people may experience dry mouth, nausea, or diarrhea (1). One study reported that a patient had developed a systemic allergic reaction after taking a strain of cultivated *C. sinensis* called Cs-4 (61); however, this type of reaction is not common. There is little published data on the use of *Cordyceps* spp. in pregnant or lactating women, or in very young children, and appropriate precautions should be taken with these types of patients.

Toxicity

No human toxicity has been reported, and animal models failed to find an LD₅₀ (median lethal dose) injected IP in mice at up to 80 g/kg per day, with no fatalities after seven days (2). Given by mouth to rabbits for three months, at 10 g/kg per day ($n = 6$), no abnormalities were seen from blood tests or in kidney or liver function (62).

REGULATORY STATUS

Cordyceps spp. remains, in many nations throughout the world, an unrecognized substance. Other than import/export taxes and restrictions, which vary from country to country (many of which ban the import of any such substance), most governments do not require a prescription to purchase or use *Cordyceps* spp. Among the few countries that do require a doctor's prescription are Portugal, Romania, and Austria. Many governments require that vendors obtain a special license to distribute any product relating to human health.

In the United States, *Cordyceps* spp. are marketed privately and considered by the FDA as a dietary supplement. GRAS applications referring to *Cordyceps* spp. status as a food additive are unavailable; however, a premarket notification to the FDA regarding species of *Cordyceps*, containing in-depth information relating to preclinical trials and toxicology studies, has been available to the public, via the FDA website.

CONCLUSIONS

When a natural product, such as *C. sinensis*, has such a long history of use, it seems logical that there is quite likely some truth behind the myths. Our challenge in the modern age is to scientifically unravel the many claims and conflicts. With *C. sinensis* this challenge has been greater than with many other herbals due to the enormous cost and scarcity of the material. We are fortunate that we live in an age of such rapidly expanding biotechnological progress. For now, we have ways at our disposal to produce *Cordyceps* spp. in large enough volume, and at a low enough cost, that research becomes possible to nearly anyone interested in looking at this unique organism. As time passes, we may find that this once rare fungal species may hold the key to controlling some of our more difficult to manage diseases. More research is needed into this and other species of medicinal mushrooms.

Cranberry

Marguerite A. Klein

INTRODUCTION

Cranberry (*Vaccinium macrocarpon* Aiton) is a native plant of North America. Today, it is one of the top selling herbal supplements in the U.S. market. Juice and dietary supplements derived from the berry reportedly exhibit various health benefits, including prevention and treatment of bacterial adhesion in urinary tract infections (UTIs) and stomach ulcers, prevention of dental caries, protection against lipoprotein oxidation, and anticancer activity. Some of these biologic effects have been linked to the presence of phenolic compounds. The composition of these compounds in cranberry is beginning to be assessed and quantified; however, their bioavailability and metabolism are for the most part not known. Interpretation of results from research on the efficacy/safety profile of cranberry is confounded by methodologic limitations. More research is needed to conclusively determine its health benefits.

BACKGROUND

V. macrocarpon Aiton, the cultivated species, is a member of the heath family (Ericaceae), which includes blueberry, huckleberry, and bilberry. The wild plants are distributed over eastern United States and Canada. Cranberry was of great economic value to the Native Americans, especially since it was the only edible fruit available late in the season (September–November). Various parts of the plant were used as dyes, food, and medicines. They used the berries in poultices for treating wounds and blood poisoning; the leaves for urinary disorders, diarrhea, and diabetes; and infusion of branches for pleurisy (1). In addition, the European settlers applied cranberries therapeutically for the relief of blood disorders, stomach ailments, liver problems, vomiting, appetite loss, and cancer. Sailors took barrels of the fruit to sea to prevent scurvy. Over 100 years ago, women in Cape Cod were known to use it for the treatment of dysuria. About four decades back, consumption of the berry for treatment of UTI received attention and support within the medical community (2,3).

Cranberry was first cultivated in the early 19th century. The principal areas of cultivation in North America are Wisconsin, Massachusetts, New Jersey, Oregon, and Washington, as well as parts of Canada. In the 1940s, cranberry juice cocktail became widely available and is the most common form of cranberry consumption today (1). This is a sweetened beverage of about 27% cranberry

juice by volume. As a dietary supplement, cranberry ranks among the top 10 selling herbal products in the U.S. market, with U.S. sales skyrocketing in 2007 by 15% (4). Also in 2007, cranberry supplements were among the top 20 supplements used by adults and children, who used non-vitamin, nonmineral, natural products for health reasons (5). Concurrent with increasing sales, publication of original scientific results, papers, and reviews almost doubled between 2004 and 2009 compared to the previous five-year period.

CHEMISTRY AND PREPARATION OF PRODUCT

The chemical composition for the nutrient constituents (Table 1) of cranberry has been well documented (6,7). Raw cranberries are relatively low in sugar content and minerals compared to other small fruits. They are a very good source of vitamin C, have a fair amount of vitamin A, but are relatively low in the B vitamins.

Most of the biologic effects of cranberry have been linked to its high level of phenolic compounds (8–11), higher than 20 other fruits tested (12,13). The major phenolics in the berry are flavonoids and phenolic acids. Chen et al. (11) found a total of 400 mg of total flavonoids and phenolic compounds per liter of sample in freshly squeezed cranberry juice. About 44% were phenolic acids and 56% flavonoids.

Phenolic acids include the cinnamic acids (C6–C3) and benzoic acids (C7). Cinnamic acids occur naturally in combination with other compounds, usually in the form of esters. The ester of caffeic with quinic acid is a classic example. On the contrary, benzoics usually occur as free acids. Benzoic acid is the major “phenolic” compound in cranberry (11). The fruits’ astringency is attributable to high levels of organic acids, primarily quinic, citric, malic, and benzoic.

Cranberries contain three major subclasses of flavonoids: flavanols, flavonols, and anthocyanidins (Table 2) (8,9).

Flavanols exist in the monomer form (catechin and epicatechin) and the oligomer or polymer form (proanthocyanidins). Proanthocyanidins, also known as condensed tannins, are polymeric compounds, the basic structural elements of which are polyhydroxyflavan-3-ol units linked together by carbon–carbon bonds (14). Unlike most fruits, cranberry contains a relatively high proportion of A-type proanthocyanidins (13,15). One subclass of proanthocyanidins is procyanidins. Cranberries contain a

Table 1 Nutrient Content of *Vaccinium macrocarpon*

Source (100 g)	Water (g)	Energy (kcal)	Total sugars (g)	Ca (mg)	Mg (mg)	K (mg)	Vitamin C (mg)	Thiamin (mg)	Riboflavin (mg)	Vitamin A (IU)	Vitamin E (mg)

IU, International Units.

Source: From Refs. 6, 7.

variety of different procyanidins, mixtures of oligomers and polymers, with the last of these being the dominant procyanidins in cranberry (16). Procyanidins may contribute to organoleptic characteristics.

Flavonols include the glycosides of quercetin, kaempferol, and myricetin (11,17). Quercetin is the major flavonol in cranberry and is glycosylated mainly at the 3-position with arabinose, galactose, rhamnose, and rhamnose-glucose. Myricetin also exists and has been identified as conjugates of both arabinose and galactose (18). The wide-ranging flavonol content of cranberry is high, exceeding 150 mg/kg (17).

Anthocyanins, glycosylated anthocyanidins, are responsible for the fruit's bright red color. Early studies found a somewhat higher content of anthocyanins than flavonols (19). The pigments present are cyanidin-3-galactoside, -3-glucoside, and -3-arabinoside, as well as peonidin-3-galactoside, -3-glucoside, and -3-arabinoside (20). The major anthocyanins in cranberry are 3-galactosides and 3-arabinosides of cyanidin and peonidin (21).

Uniform requirements for the composition of cranberry products do not exist. In addition to the variable composition of the berries, processing and the product matrix contribute to product composition variability that may impact stability and bioactivity. Characterization and standardization of the bioactive constituents in cranberry products are needed to help in determining product stability and to allow comparison among studies. However, quantification is not always straightforward. A broad spectrum of methods is used to quantify the constituents, leading to differing results. Finally, no cranberry-standardized reference materials to which results of different analytic methods can be compared are available (22,23).

PRECLINICAL STUDIES

Bioavailability

The structural diversity of cranberry components has a major influence on their bioavailability, which in turn influences their biologic effects. Many studies have ignored

their achievable plasma concentration after ingestion as well as the possibility of conjugation and metabolism of bioactive components. In general, polyphenols reaching the colon are extensively metabolized by microflora into a wide array of low-molecular-weight phenolic acids. The concentration of intact polyphenols (parent compounds and their conjugated forms) in plasma rarely exceeds 1 $\mu\text{mol/L}$ (1 μM) after consumption of a single compound. However, measurement of plasma antioxidant capacity suggests that more phenolic compounds are present, largely in the form of unknown metabolites, produced either in the tissues or by gut microflora. Their urinary recovery has been found in the range of 1% to 25% of ingested amount (21).

The bioavailability of the major flavonoids from cranberry has not been studied. However, their bioavailability from other dietary sources (e.g., tea, cocoa or chocolate, red wine, onions, or fruits) has been analyzed (24–26). Less is known about absorption and metabolism of the proanthocyanidins than other flavanols, in part due to their complex structures and nonspecific analytic methods to detect them. Higher molecular weight polymers are considered to have poor absorption (27,28). Proanthocyanidins are degraded to low-molecular-weight metabolites by human colonic microflora (29). Although biologic activity is apparent after proanthocyanidin ingestion, only its metabolites have been measured in the urine and plasma (29).

Urinary Acidification

Cranberries contain quinic acid, which is excreted in the urine as hippuric acid. Early studies attributed the antibacterial nature of the fruit to the urinary acidifying activity due to the excretion of organic acids and increased concentration of hippuric acid (30–32). Other experiments showed no decreased pH, nor increased levels of hippuric acid or only a brief effect (33–35). Hippuric acid does have antibacterial effects if present in acidic urine (pH 5.0) and at concentrations of 0.02–0.04 M. However, cranberry juice rarely can achieve the bacteriostatic concentrations by itself without the addition of exogenous hippuric acid to the diet (36,37).

Table 2 Flavonoid Content of *Vaccinium macrocarpon* (mg/100 g)

Source	Anthocyanidins		Flavanols		Flavonols		Proanthocyanidins	
	Cyanidin	Peonidin	(–)-Epicatechin	(+)-Catechin	Myricetin	Quercetin	Monomers	Polymers
Cranberries, raw	41.81	42.10	4.37	0.39	6.78	15.09	7.26	233.48
Cranberry juice cocktail	0.38	NA	NA	0.19	0.51	1.27	0.56	8.33

Antiadhesion in Urogenital Infections

In vitro and ex vivo studies indicate that cranberry products prevent adhesion of bacteria to the cell walls of the urinary tract, thus preventing UTIs. Emphasis has been on the role of components that act by interference with bacterial adherence of *Escherichia coli* to uroepithelial cells (38–40). Several ex vivo studies found antiadherence activity in mouse and human urine (15,38,41–43). Two compounds were identified that inhibited adherence. One was fructose and the other was a nondialyzed polymeric compound present only in cranberry. While fructose in vitro inhibits adherence (38,40), it is unlikely to contribute to in vivo antiadhesion activity in urine because it is metabolized before reaching the urinary tract. The nondialyzed polymeric compound proved to be A-type proanthocyanidins. This compound, but not B-type dimer or the (–)-epicatechin monomer, prevented uropathogenic *E. coli* from adhering to uroepithelial cells in vitro (14,39,44).

Subsequently, isolated proanthocyanidins and whole cranberry products have been shown to inhibit *E. coli* adherence to model systems of primary cultured bladder and vaginal epithelial cells in a dose-dependent fashion, including clinically achievable doses (240 mL cranberry juice cocktail). However, only a very small portion of a dose may reach the bladder (45) and possibly not even excreted intact in the urine (46). A new group of urinary marker compounds, discovered by a robust antiadhesion assay, include two new coumaroyl iridoid glycosides and a depside (47). Furthermore, it is not known if any cranberry constituents reach vaginal tissues (45).

In conclusion, to date no specific antiadherent cranberry constituents or metabolites, proanthocyanidin or otherwise, in the urine have been elucidated, and possible synergism among constituents needs to be considered.

Dental Plaque

Cranberry compounds, alone or combined, may have the potential to inhibit the development of dental plaque (biofilm) and to prevent or reduce the severity of periodontal disease. Nondialyzable, high-molecular-weight cranberry compounds (anthocyanins and proanthocyanidins in combination) may limit extracellular matrix degradation and other pathologic processes leading to periodontal disease. In vitro studies of this test material showed it having a high capacity to inhibit proteolytic enzyme activity of specific metalloproteinases and elastase, as well as to inhibit production of metalloproteinases (48). These enzymes play a major role in gingival tissue destruction, connective tissue remodeling, and alveolar bone resorption. Their secretion from host cells may, in part, be stimulated by components of the dental biofilm.

The pathogenesis of dental caries involves an interaction of diet constituents with microorganisms, which occurs within dental plaque. *Streptococcus mutans* is considered the primary microbial agent in this pathogenesis. It has two virulent traits: (i) synthesis of extracellular polysaccharides (glucans) through glucosyltransferases, and (ii) ability to produce and tolerate acids, both of which lead to cariogenic biofilms. Cranberry juice, crude extracts, and semipurified materials composed of low- and/or high-molecular-weight compounds have been shown in vitro to disrupt the virulent traits of *S. mutans* and

Porphyromonas gingivalis (49–52). Eleven isolated, highly purified, low-molecular-weight cranberry constituents (including flavonols, phenolic acids, and proanthocyanidins) were tested alone and in combination to investigate which compounds influenced the virulence properties of *S. mutans* associated with glucan synthesis and acidogenicity (53). Phenolic acids showed little effect. However, specific flavonoids and proanthocyanidins resulted in moderate, statistically significant effects. Furthermore, certain combinations of these low-molecular-weight compounds appeared to have an additive effect.

Helicobacter pylori Infection

Several mechanisms by which cranberry constituents may prevent or treat *Helicobacter pylori* infections have been examined and hypothesized, including (i) interference of bacterial adhesion, (ii) inhibition of cell growth and/or colonization, (iii) exerting bactericidal activities, (iv) induction of the bacteria to develop a coccoid (spheroid) form, and (v) neutralization of gastric pH.

Adhesins mediate adhesion of *H. pylori* to epithelial cells. Because cranberry or its constituents have been shown to inhibit adherence of *E. coli* to uroepithelial cells in vitro, it has been hypothesized that it would prevent adhesion of *H. pylori* to gastric mucus and cells. A high-molecular-weight, nondialyzable material from cranberry juice was demonstrated to restrain the adhesion of two-thirds of the tested strains of *H. pylori* to immobilized human gastric mucus and erythrocytes (54,55).

Preliminary results indicate that cranberry phenolics may disrupt energy production and cause cell death (56). In addition, cranberry phenolics may inhibit urease activity. *H. pylori* releases the enzyme urease, which converts urea into ammonia in the stomach. This neutralizes the pH and protects *H. pylori* from stomach acid. Finally, the *H. pylori* inhibiting factor may not be unique to cranberry but common to all polyphenol-rich fruits (56,57). These in vitro effects have been demonstrated in animal models, with the administration of cranberry juice resulting in the eradication of the pathogen; however, mechanisms and specific cranberry constituents remain to be elucidated.

Antioxidant

Antioxidant capacity is not restricted to a particular class of cranberry components but has been found in a wide range of fractions (58). Polyphenols are reducing agents, and together with others, such as vitamin C, they may protect the body's tissues against oxidative stress. The antioxidant activity of the berry in vivo cannot be accounted for on the basis of increased vitamin C alone (59). Crude cranberry fruit extracts have significant antioxidant activity in vitro (60). The total antioxidant activity of 100 g of cranberry was estimated to be equivalent to that of 3120 mg of vitamin C (12). Isolated polyphenolic compounds from whole cranberries are comparable or superior to that of vitamin E in their activity (18). Cranberry ranks higher than apple, peach, lemon, pear, banana, orange, grapefruit, pineapple, avocado, cantaloupe, melon, nectarine, plum, and watermelon (13,61,62). However, cranberry juices ranked lower in antioxidant potency using a variety of antioxidant tests than many other leading U.S. brands of ready-to-drink, polyphenol-rich beverages,

including pomegranate juice, red wine, Concord grape juice, blueberry juice, black cherry juice, and Acai juice (62). In comparing cranberry products to one another, it appears that processing decreases the quality of antioxidants. The quality is the result of changing the polyphenol composition and is independent of the quantity of antioxidants present (63).

The contribution of individual phenolics to total antioxidant capacity is generally dependent on their structure and content in the berry. The highest antioxidant activity has been noted in peonidin-3-galactoside (21% of antioxidant capacity). Quercetin-3-galactoside, cyanidin-3-galactoside, and peonidin-3-arabinoside each contribute about 10% to 11% (64). These four flavonoids have the most potent antioxidant activities compared to 16 other isolated compounds, including plant sterols, other flavonoids, derivatives of triterpenoids, and organic acids. The isolated compounds may have additive and synergistic effects (65). Animal model studies have shown whole-body antioxidant potential at clinically relevant doses and with dose-dependent responses (66,67).

Different methods of assessment of antioxidant capacity, varying substrate systems, divergent ways of extraction, length of storage, and differential concentrations of active antioxidants confound the antioxidant activity–chemical structure relationship. Given the diversity and abundance of phenolic antioxidants in cranberry, considerable potential exists for cranberry products to prevent oxidative processes related to cardiovascular disease and cancer at the cellular level and in vivo.

Atherosclerosis

Consumption of cranberry may decrease the risk of atherosclerosis (68). Possible mechanisms by which cranberry may reduce risk include: (i) inhibition of low-density-lipoprotein (LDL) oxidation (18,63), (ii) inhibition of platelet aggregation and adhesion, (iii) inhibition of the inflammatory response, (iv) induction of endothelium-dependent vasodilation, and (v) increase of reverse cholesterol transport and decrease of total and LDL cholesterol. Data supporting these mechanisms are preliminary and mostly from in vitro and animal model studies (69,70). In vitro studies suggest that molecules like quercetin, resveratrol, proanthocyanidin, anthocyanidin, hydroxycinnamic acid, and acetylsalicylic acid may contribute to an anti-inflammatory response. Human studies have shown that cranberry increases total antioxidant capacity, reduces plasma oxidized LDL (but not total LDL), and reduces cell adhesion molecules (71,72). It has been hypothesized that the potential effect of cranberry on atherosclerosis may result from additive or synergistic effects of multiple cranberry constituents due to various mechanisms and not just the antioxidant effect alone. The constituents contributing to the antioxidant effect were previously addressed.

Cancer

The antioxidant capacity alone of cranberry constituents may not account for the observed effects (61,73,74). A soluble-free cranberry extract had the highest antiproliferative activity and maximum calculated bioactivity index for dietary cancer prevention compared to 10 other fruits

(12). Many of the cranberry compounds are likely contributors, including the flavonols, anthocyanins, proanthocyanidins, catechins, various phenolic acids, triterpenoids (e.g., ursolic acid), and even stilbenes (e.g., resveratrol) although these are present in lesser quantities than the other constituents (65,70). Cranberry's effect on tumor initiation, growth, and metastases will depend largely on the bioavailability of its phytochemicals to the various target tissues.

Given the diversity of molecular structures and bioactivity among the classes of phytochemicals in cranberry, it is likely that they may fight cancer individually, additively, or synergistically by several different mechanisms. In vitro evidence in a variety of cell lines exists for possible mechanisms, including (i) induction of apoptosis in a variety of cancer cells, (ii) reduction of invasion and metastasis by inhibition of matrix metalloproteinases, (iii) inhibition of ornithine decarboxylase expression and activity, (iv) inhibition of angiogenesis, (v) inhibition of inflammatory processes, and (vi) inhibition of *H. pylori*, a risk factor for gastric cancer (58,61,70,72,74–76). In vivo carcinogenesis studies will need to be performed to further confirm antitumor promotion activity and identify individual components and mixtures responsible for activity.

Safety Studies

No animal toxicology studies of any cranberry products have been reported; however, two studies have reported on safety in animal models. A mouse model study of the effect of cranberry extract on cancer treatment reported weight loss indicative of toxicity (77). A safety study of a single oral dose of a proprietary multiberry supplement, including cranberry (66), did not cause any mortality and did not demonstrate any signs of gross toxicity, adverse pharmacologic effects, or abnormal behavior in the treated rats. Similarly acute dermal toxicity, primary skin irritation, primary eye irritation via nonoral routes of administration caused no toxicity or harm in animal models.

CLINICAL STUDIES

Efficacy

Urinary Tract Infection

The use of cranberry, particularly as a juice or juice cocktail, to prevent or treat UTI is common. The accumulating evidence from small, noncontrolled, and controlled clinical trials suggests that the berry may relieve symptoms associated with UTI and may reduce the need for antibiotics. The Cochrane Library conducted separate reviews of the fruit for the prevention (78) and treatment (79) of UTI. For *treatment*, no trials meeting the inclusion criteria were found; only a few uncontrolled trials were found. The Cochrane Library concluded that there was no good quality or reliable evidence of the effectiveness of cranberry juice or other cranberry products for the treatment of UTI. For both prevention and treatment, the review authors concluded that more research was needed. For *prevention*, 10 studies were included in the review, of which only four were of sufficient methodological quality to include in the meta-analysis. Juice, juice cocktail, or concentrate was investigated in seven studies and capsules or tablets

studied in four trials (one study investigated both juice cocktail and tablets). Intervention duration ranged from four weeks to one year and dosage was quite variable. Several studies reported a high number of withdrawals, and poor adherence to the intervention was also reported. Side effects were common in all studies. The authors concluded that cranberry products may decrease the number of symptomatic UTIs over 12 months.

The National Institutes of Health (NIH) supported four, large Phase 2 clinical studies to investigate the effect of a research-grade, low-calorie cranberry juice cocktail on the prevention of UTI in men and nonpregnant women at high risk for UTI and in pregnant women. Subsequent to the Cochrane reviews, results of the cranberry juice cocktail study of asymptomatic bacteriuria in pregnancy have been reported (80). Similar to other studies, a high number of dropouts/withdrawals occurred and adherence to the intervention protocol was poor which led to a protocol change to reduce the dose of 240 mL (80 mg proanthocyanidin) from three to two times a day. Despite the limitation of the protocol change and problems with withdrawal, adherence, and intervention tolerability, the data suggest that cranberry juice cocktail may be protective of asymptomatic bacteriuria and symptomatic UTIs in pregnancy. Results from the other three NIH-supported trials will be reported.

Many of the clinical study reports, with the exception of the NIH-sponsored studies, suffer from major limitations. Many trials have not been controlled or randomized, and randomization procedures have not always been described. Crossover designs used in some research may not be appropriate for studies of UTI. Other limitations include no blinding or failed blinding, lack of controlled diets or dietary assessment, use of convenience samples, and small numbers of subjects. Trials have been faulted for the large number of withdrawals. Intention-to-treat analyses were not often applied. Most studies have been conducted in older or elderly patients. Very few have been conducted in younger patients, with or without comorbidities, or in men. Primary outcomes have differed from study to study and have often included urinary pH, as well as rate of bacteriuria, biofilm load, and urinary white and red blood cell counts, rather than UTI. It is also not clear what the optimum dosage or type of product is. There is limited evidence of efficacy or safety for forms of cranberry product other than juice or juice cocktail. Finally, the published articles do not describe the quality and composition of the products tested.

***H. pylori* Infection**

A few randomized controlled studies of *H. pylori* infected male and female adults and children have been undertaken in China, Israel, and Chile with treatment outcomes determined by the C urea breath test as the gold standard to noninvasively detect active *H. pylori* infection (81–83). Although study limitations exist and generalizability is limited, results are encouraging and suggest that regular consumption of cranberry juice as a complement or alternative to standard triple therapy (a combination of antibiotics and a proton pump inhibitor) may suppress *H. pylori* infection. The studies suggest that females may be more responsive and that the effect may not persist when cranberry treatment is discontinued.

Adverse Effects

The U.S. Food and Drug Administration granted generally recognized as safe (GRAS) status to cranberry foods and beverages. This means that their safety is well established when consumed in food amounts. The safety or harm of dosages higher than food amounts cannot be confirmed without further high quality clinical studies. The safety of cranberry capsules, tablets, and concentrates, for example, in which doses could reach pharmacologic levels, has not been established.

The Cochrane reviews of UTI prevention and treatment indicated that side effects were common in all cranberry juice cocktail studies included in the reviews (78,79). The reported side effects were primarily diarrhea or frequency of bowel movements and other gastrointestinal symptoms.

A review of the safety of cranberry consumption by pregnant and lactating women indicated that there were no clinical studies in the evidence-based medicine literature of cranberry being either safe or contraindicated during pregnancy or lactation (84). Subsequent to the review, the first randomized, controlled trial of cranberry juice cocktail for the prevention of bacteriuria in pregnancy reported about 20% withdrawal due to gastrointestinal upset, including nausea, vomiting, diarrhea, at a dose of 240 mL three times a day (80). When the dose was reduced to two times a day, the juice cocktail was somewhat better tolerated. There were no differences between the active and placebo groups with regard to obstetric or neonatal outcomes.

Observed Drug Interactions and Contraindications

There is insufficient reliable information available on cranberry dietary supplements or juice cocktail to assess their safety or their interaction with other dietary supplements, foods, medications, or laboratory tests.

Because of its oxalate levels, cranberry may be a causative factor in nephrolithiasis. The results of two small studies of juice cocktail and tablets are equivocal, showing differences in urine acidification, calcium and oxalate excretion, and other promoters and inhibitors of stone formation (85,86). A third study (87) was designed to specifically assess the influence of diluted cranberry juice on urinary biochemical and physicochemical risk factors for calcium oxalate kidney stone formation. Three key urinary risk factors were favorably altered: (i) oxalate (reported to not be readily bioavailable from cranberry juice) excretion decreased, (ii) phosphate excretion decreased, and (iii) citrate (an inhibitor of stone formation) excretion increased.

There is one report of an infant hospitalized for cranberry juice intoxication and acidosis (88).

Theoretically, the juice could interfere with the copper-reduction glucose test because ascorbic acid (a reducing agent) and hippuric acid have each been reported to cause a false-positive reaction with the copper-reduction glucose determination in vitro. However, the results of two small studies are equivocal and inconclusive indicating that interference may be variable and dependent on the type of reagent strip kit (89,90).

Limited studies have evaluated the drug interaction potential of cranberry juice; no studies of cranberry supplements are reported. The present hypothesis exerts that constituents of cranberry and/or their metabolites may

interact with liver CYP isoenzymes or with intestinal and renal drug transporters to alter the pharmacokinetics of drugs. Factors that alter the metabolism of drugs play an important role in dosing.

Only one study to date has examined the interaction of cranberry and antibiotics commonly prescribed for recurrent UTIs, amoxicillin and cefaclor (91). This study of healthy women showed a modest delay in amoxicillin absorption and a slight delay in cefaclor absorption, neither delay being clinically significant. Their total absorption and renal clearance were not affected.

Causal relationships cannot be proved by case reports; however, they often help in identifying adverse events and drug interactions. In 2003, the United Kingdom's Committee on Safety of Medicines alerted health care professionals about the possibility of an interaction between cranberry juice and warfarin, the most commonly prescribed oral anticoagulation therapy (92). Five unsubstantiated reported cases suggested an interaction (92). By 2004, the Committee had received 12 anecdotal case reports of suspected interaction and concluded that there was sufficient evidence of interaction, even though the evidence was not credible (93).

It now appears that reports of enhanced antithrombotic effects of warfarin associated with cranberry juice administration may be a coincidence; however, there is inconsistency among study findings. To address the effect of cranberry on CYP2C9, evaluations have been conducted in vitro and in vivo. In vitro studies have shown that cranberry juice potentially inhibits CYP3A and CYP2C9 (94,95). On the other hand, a number of in vivo human studies reported no alteration of warfarin pharmacokinetics (95–99). In addition, studies of coadministration of cranberry with other drugs primarily metabolized by CYP2C9 (95,99) or metabolized by CYP3A (100) or CYP1A2 (96) similarly show no pharmacokinetic change. There does remain, nevertheless, potential drug interaction liability with cranberry (101), because inconsistencies among studies may be due to participant characteristics, dosing, intervention duration, variability of cranberry test materials, physiochemical effects of cranberry on drug absorption, study design, and sample size. Worthy of further investigation is the new evidence of genotype-dependent interactions with warfarin (97).

Because information concerning the influence of cranberry juice on the pharmacokinetics of CYP2C9 substrates is limited, it may be premature to reach a definite conclusion about the effect of cranberry juice on warfarin pharmacokinetics. Nevertheless, patients who are coadministered warfarin and especially large doses of cranberry (102) should be monitored for the most appropriate therapeutic range.

REGULATORY STATUS

In the United States, cranberry is classified as a food when sold as juice, juice cocktail, and other conventional forms. Cranberry products, such as encapsulated powders, tablets, or tinctures, are regulated as "dietary supplements" in the United States. In Canada, conventional forms are sold as foods, whereas products promoting a health claim are sold as "natural health products."

CONCLUSIONS

There is a need for comprehensive chemical analyses of all classes of compounds present in cranberry. Individual structures and composition vary significantly among cranberry products and its isolated constituents. Composition varies by ripeness of the fruit, plant variety, growth conditions, extraction method, and processing. This suggests that bioactivities will also vary. However, quantitation of complex polyphenols has been and continues to be limited because of the lack of appropriate standardized analytical methods. Consequently, the precise estimation of cranberry constituent intake is hampered. Furthermore, the bioavailability, metabolism, stability, purity, and composition of cranberry products tested in clinical studies have not been established or published. Therefore, the ability to infer epidemiological relationships with health and disease can be confounded.

Evidence for health benefit of cranberry is preliminary and inconclusive. Current evidence from in vitro and clinical studies has been conflicting. This could reflect differences among sources of cranberry or its constituents, form of product consumed, and level of intakes. In addition, clinical studies performed to date have had many methodological limitations and few have assessed safety. Nevertheless, results of clinical studies are encouraging for the relief of symptoms associated with and the prevention of UTI.

The complex composition of cranberry creates problems in extrapolation of research results on dietary intake of individual constituents to intake of whole fruits or extracts of whole fruits. Synergistic effects of the whole may enhance the health benefits beyond what can be achieved by the individual constituents. The complex mixture of compounds could also protect against side effects. More research on potential synergistic and protective effects among the classes of compounds in cranberry and with other food constituents and pharmaceuticals is necessary.

For these reasons, it is important to understand the composition of cranberry, determine the bioavailability and metabolism of its constituents in isolation and as part of the whole mixture, and rigorously examine the biologic effects of cranberry on disease conditions in order to establish its potential for being safe and providing health benefit.

Creatine

G. S. Salomons, C. Jakobs, and M. Wyss

INTRODUCTION

Creatine (Cr)—methylguanidino acetic acid—is a naturally occurring compound that was first described by Chevreul in 1832. Its name is derived from the Greek word *kreas* (flesh). Creatine is found in abundance in skeletal muscle (red meat) and fish. It is essential in energy transmission and storage via creatine kinase (CK). The daily Cr dosage is obtained by both endogenous synthesis and via nutritional intake, followed by absorption in the intestine (1). Creatine supplementation is widespread among sportspersons because of its documented and/or presumed ergogenic effects (2–4). In addition, supplementation with Cr has proven to be instrumental for the treatment of rare inborn errors of metabolism due to defects in Cr biosynthesis enzymes (5–8).

Creatine is stored in high concentrations in skeletal and heart muscles and to a lesser extent in the brain. It exists in both free and phosphorylated form [phosphocreatine (PCr)] and is important for maintaining high ratios between adenosine triphosphate (ATP) and adenosine diphosphate (ADP). Upon increases in workload, ATP hydrolysis is initially buffered by PCr via the CK reaction. During high-intensity exercise, PCr in muscle is depleted within several seconds. Whether *de novo* Cr biosynthesis occurs in the brain or whether Cr is taken up into the brain through the blood–brain barrier, is currently a matter of debate.

DEFICIENCY AND SUPPLEMENTATION

Patients with Cr deficiency syndromes (CDS), that is, patients with a Cr biosynthesis defect or a Cr transporter defect, have developmental delay and mental retardation (MR), indicating that Cr is crucial for proper brain function. Surprisingly, however, CDS patients do not suffer from muscular or heart problems. Those with a Cr biosynthesis defect, in contrast to Cr transporter-deficient subjects, can partly restore their Cr pool in brain upon Cr treatment (5–10).

Creatine supplementation, due to its ergogenic effects, has become a multimillion dollar business (3). In the Western world, Cr has received wide public interest. A simple search on “creatine” in the World Wide Web using common database search engines results in more than 500,000 entries. Besides the use by sportspersons, Cr supplementation is explored in several animal models of neuromuscular disease (i.e., Huntington and Parkinson disease, amyotrophic lateral sclerosis) and in human disease (3,6,11,12). A recent study suggests that Cr supplementa-

tion increases intelligence and memory performance tasks (13).

The goal of this entry is to provide an overview on Cr and its metabolism in health and disease. The functions of Cr and PCr, Cr biosynthesis, its degradation, tissue distribution, transport and molecular aspects, as well as the benefits and risks of Cr supplementation are discussed. (For in-depth reviews, see Refs. 2, 3, 6 and references therein.)

BIOCHEMISTRY AND FUNCTION

Creatine Structure

Creatine is a naturally occurring guanidino compound. Its chemical structure is depicted in Figure 1. Creatine is a hydrophilic, polar molecule. Phosphocreatine is zwitterionic, with negatively charged phosphate and carboxylate groups and a positively charged guanidino group.

Creatine Synthesis

Biosynthesis

The transfer of the amidino group of arginine to glycine yielding L-ornithine and guanidinoacetic acid (GAA) represents the first step in the biosynthesis of Cr and is performed by L-arginine:glycine amidinotransferase (AGAT; EC 2.1.4.1). This reaction is reversible and occurs in mitochondria, into which arginine has to be taken up for guanidinoacetate biosynthesis. The human *AGAT* mRNA encodes a 423-amino acid polypeptide including a 37-amino acid mitochondrial targeting sequence. The *AGAT* gene is located on chromosome 15q15.3, is approximately 17 kb long, and consists of 9 exons.

The second step involves the methylation of GAA at the amidino group by (S)-adenosyl-L-methionine:N-guanidinoacetate methyltransferase (GAMT; EC 2.1.1.2), whereby Cr is formed. The methyl group is provided by (S)-adenosylmethionine. The human *GAMT* mRNA encodes a 236-amino acid polypeptide. The gene is located on chromosome 19p13.3, is approximately 12 kb long, and consists of 6 exons.

Chemical synthesis

Creatine is produced by chemical synthesis, mostly from sarcosine and cyanamide. This reaction is prone to generation of contaminants such as dicyandiamide, dihydrotriazines, or Crn (14). Some manufacturers may fail to separate these contaminants from Cr. The toxicological profiles of these contaminants are often not known. Dicyandiamide liberates hydrocyanic acid (HCN) when exposed to strongly acidic conditions (such as in the stomach). For human consumption, only pure preparations of Cr should thus be allowed. Unfortunately, no generally accepted and

Figure 1 Schematic representation of the creatine kinase (CK) reaction, and chemical structures of creatine (Cr) and phosphocreatine (PCr).

meaningful quality labels are yet in place that would allow a consumer to judge the origin and quality of Cr in a given commercial product. Moreover, for most studies published so far, it is not possible to correlate the presence or lack of ergogenic, preventive, or adverse side effects with the quality of the many Cr preparations used.

Creatine Function (CK Reaction)

Creatine is involved in ATP regeneration via the CK reaction. The phosphate group of PCr is transferred to ADP to yield Cr and ATP, the “universal energy currency” in all living cells. The CK reaction serves as an energy and pH buffer and has a transport/shuttle function for high-energy phosphates.

Several CK subunits exist that are expressed in a tissue- and/or spatial-specific manner. In mammals, four CK isoforms exist: the cytosolic M-CK (M for muscle) and B-CK (B for brain) subunits form dimeric molecules, that is, the MM-, MB-, and BB-CK isoenzymes. The two mitochondrial CK isoforms, ubiquitous Mi-CK and sarcomeric Mi-CK, are located in the mitochondrial intermembrane space and form both homodimeric and homo-octameric interconvertible molecules.

In fast-twitch skeletal muscles, a sizeable pool of PCr is available for immediate regeneration of ATP, which is hydrolyzed during short periods of intense work. In these muscles, the cytosolic CK activity is high and “buffers” the cytosolic phosphorylation potential that seems to be crucial for the proper functioning of a variety of reactions driven by ATP. Slow-twitch skeletal muscles, the heart, and spermatozoa depend on a more continuous delivery of high-energy phosphates to the sites of ATP utilization. In these tissues, distinct CK isoenzymes are associated with sites of ATP production (e.g., Mi-CK in the mitochondrial intermembrane space) and ATP consumption [e.g., cytosolic CK bound to the myofibrillar M line, the sarcoplasmic reticulum, or the plasma membrane] and fulfill the function of a “transport device” for high-energy phosphates. The γ -phosphate group of ATP, synthesized within the mitochondrial matrix, is transferred by Mi-CK

in the mitochondrial intermembrane space to Cr to yield ADP and PCr. ADP may directly be transported back to the matrix where it is rephosphorylated to ATP. Phosphocreatine leaves the mitochondria and diffuses through the cytosol to the sites of ATP consumption. There, cytosolic CK isoenzymes locally regenerate ATP and thus warrant a high phosphorylation potential in the vicinity of the respective ATPases. Subsequently, Cr diffuses back to the mitochondria, thereby closing the cycle. According to this hypothesis, transport of high-energy phosphates between sites of ATP production and ATP consumption is achieved mainly by PCr and Cr. The CK system is required to allow most efficient high-energy phosphate transport, especially if diffusion of adenine nucleotides across the outer mitochondrial membrane is limited.

Physiology

Tissue Distribution of Creatine and of Its Biosynthesis Enzymes

In a 70-kg man, the total body creatine pool amounts to approximately 120 g (1). Creatine and PCr are found in tissues with high and fluctuating energy demands such as skeletal muscle, heart, brain, spermatozoa, and retina. In skeletal and cardiac muscle, approximately 95% of the total bodily Cr is stored, and the concentration of total creatine may reach up to 35 mM. Intermediate levels are present in brain, brown adipose tissue, intestine, seminal vesicles and fluid, endothelial cells, and macrophages. Low levels are found in lung, spleen, kidney, liver, white adipose tissue, blood cells, and serum (25–100 μ M) (2).

Until recently, GAA biosynthesis was presumed to occur mainly in the kidney (and pancreas), where AGAT is highly expressed, followed by its transport via the blood and uptake of GAA into the liver, the presumed major site of the second reaction, the methylation of GAA by GAMT. Current knowledge suggests that AGAT and GAMT expression is not limited to these organs. Synthesis outside of these organs may allow local supply of Cr (e.g., in brain; see creatine biosynthesis in mammalian brain) and may, to a minor extent, contribute to the total Cr content in the body.

Creatine Accumulation: Transporter-Mediated Creatine Uptake

Cellular transport is of fundamental importance for creatine homeostasis in tissues devoid of Cr biosynthesis. Creatine needs to be taken up against a steep concentration gradient [muscle (mM), serum (μ M)]. The Cr transporter gene (*SLC6A8*) (MIM300036) has been mapped to chromosome Xq28. Northern blots indicated that this gene is expressed in most tissues, with the highest levels in skeletal muscle and kidney, and somewhat lower levels in colon, brain, heart, testis, and prostate. The *SLC6A8* gene product is a member of a superfamily of proteins, which includes the Na⁺-dependent and Cl[−]-dependent transporters responsible for uptake of certain neurotransmitters. The Cr transporter gene spans approximately 8.4 kb, consists of 13 exons, and encodes a protein of 635-amino acids.

Creatine/Creatinine Clearance

Creatine can be cleared from the blood via either uptake into different organs by the Cr transporter or by excretion via the kidney. There is evidence that tissue uptake

of Cr may be influenced by carbohydrates, insulin, caffeine, and exercise and that transporter molecules located in kidney are able to reabsorb Cr. Nevertheless, Cr is found under normal conditions in urine in various amounts. The main route for clearance of Cr is via creatinine excretion. Creatine and PCr are nonenzymatically converted to creatinine. The rate of creatinine formation, which mainly occurs intracellularly, is almost constant (~1.7% per day of the Cr pool). Because muscle is the major site of creatinine production, the rate of creatinine formation is mostly a reflection of the total muscle mass. Creatinine enters the circulation most likely by passive transport or diffusion through the plasma membrane, followed by filtration in kidney glomeruli and excretion in urine.

Creatine Deficiency Syndromes

Both AGAT and GAMT deficiencies are autosomal recessive inborn errors of metabolism. This is in contrast to the third disorder of Cr metabolism, which is an X-linked inborn error due to a defect in the Cr transporter (Table 1).

GAMT Deficiency

The first inborn error of Cr biosynthesis, GAMT deficiency (MIM601240), was identified in 1994. The absence of a Cr signal in the proton magnetic resonance spectroscopy (¹H-MR) spectrum of brain, the low amounts of urinary creatinine, and the increased levels of GAA in plasma and urine led to the diagnosis of this disease. In addition to creatinine, Cr is also reduced in body fluids. Clinical symptoms are usually noted within the first eight months of life. Possibly Cr is provided in high amounts in utero via the umbilical cord and in newborns via the mother's milk, thereby delaying the clinical signs. All patients identified so far have developmental delay, MR to various degrees, expressive speech and language delay, epilepsy, autistic-form behavior, and very mild-to-severe involuntary extrapyramidal movements. The disorder has a highly het-

erogeneous presentation, varying from very mild signs to severe MR, accompanied by self-injurious behavior.

AGAT Deficiency

In 2001, the first family with AGAT deficiency (MIM602360) was identified. The two sisters, four and six years old presented with MR, developmental delay from the age of eight months, and speech delay. GAMT deficiency was ruled out because GAA was not increased in urine and plasma. Creatine supplementation (400 mg/kg body weight per day) increased the Cr content in the brain to 40% and 80% of controls within three and nine months, respectively. A homozygous nonsense mutation in the AGAT gene, predicting a truncated dysfunctional enzyme, was finally identified. Lymphoblasts and fibroblasts of the patients indicated impaired AGAT activity. A third related patient was identified with similar clinical presentation. The biochemical hints to detect this disorder are reduced levels of GAA (and creatinine) in plasma, cerebrospinal fluid (CSF) and possibly urine, together with reduced undetectable levels of Cr in the brain.

SLC6A8 Deficiency (Creatine Transporter Deficiency)

Like AGAT deficiency, the X-linked Cr transporter defect was unraveled in 2001. An X-linked Cr transporter (MIM300352) defect was presumed because of: (i) the absence of Cr in the brain as indicated by proton magnetic resonance spectroscopy (MRS); (ii) elevated Cr levels in urine and normal GAA levels in plasma, ruling out a Cr biosynthesis defect; (iii) the absence of an improvement on Cr supplementation; and (iv) the fact that the pedigree suggested an X-linked disease. The hypothesis was proven by the presence of a hemizygous nonsense mutation in the male index patient and by impaired Cr uptake by cultured fibroblasts. The hallmarks of this disorder are MR, expressive speech and language delay, epilepsy, developmental delay, and autistic-form behavior. The age at diagnosis of the affected males identified so far (>50) (9,15)

Table 1 Overview of CDS Based on the Listed Number of Patients

Deficiency	No. of patients	Trait	Clinical hallmarks	Metabolites	Treatment	References
AGAT (MIM602360) ^a	3, related	AR	MR Dysphasia Autistiform behavior Epilepsy	Brain: Cr ↓ ↓ in H-MRS Plasma, CSF (urine?): GAA ↓, Cr ↓	Cr supplementation	(8)

Abbreviations: AR, autosomal recessive; Cr, creatine; Crn, creatinine; H-MRS, proton magnetic resonance spectroscopy; MR, mental retardation.

varies from 2 to 66 years. In two cases, the disease-causing mutation had arisen *de novo*. In mothers and sisters who are carriers of the disease, learning and behavioral disabilities are noted in about 50% of the cases. Unfavorable skewed X-inactivation is likely the cause of the difference in severity of the clinical signs in females.

Intriguing Questions Linked to CDS

Does a Muscle-Specific Creatine Transporter Exist?

It is noteworthy that the *SLC6A8*-deficient patients do not seem to suffer from muscle and/or cardiac failure. This could indicate sufficient endogenous Cr biosynthesis in muscle. Alternatively, Cr uptake is taken over by other transporters, or a yet unknown Cr transporter exists that is specifically expressed in skeletal and cardiac muscle.

Creatine Biosynthesis in Mammalian Brain

It is a matter of debate whether Cr biosynthesis occurs in mammalian brain. The following findings suggest that it actually does: (i) In rat brain, *AGAT* and *GAMT* mRNA and protein were detected (16), (ii) The Cr content in brain of mice treated with guanidinopropionic acid, an inhibitor of the Cr transporter, was—in contrast to muscle tissues—hardly decreased. (iii) In contrast to skeletal muscle, Cr supplementation in *AGAT*- and *GAMT*-deficient patients requires months to result in an increment in Cr concentration in the brain. These findings make it unlikely that the brain is entirely dependent on Cr biosynthesis in the liver or on its nutritional intake, followed by transport through the blood–brain barrier into the brain.

However, why do Cr transporter deficient patients also reveal Cr deficiency in the brain? One explanation could be that Cr synthesis in the brain, although present, is too low to be relevant physiologically. Alternatively, the expression of *AGAT* and *GAMT* may be separated spatially (i.e., *AGAT* and *GAMT* molecules may be found in the same or different cell types, but may not be expressed in one and the same cell). This is in line with data of Braissant et al. (17) showing such spatial separation in rat brain at both the mRNA and protein level. These findings suggest that GAA needs to be taken up into the appropriate cells prior to GAA methylation, which in case of the transporter defect is not feasible. This would explain the incapability to synthesize Cr in the brain of *SLC6A8*-deficient patients. Clearly, more thorough investigations are needed to study these discrepancies toward a better understanding of Cr metabolism in the human brain.

Significance of CDS/relevance for Health Care

Mental retardation occurs at a frequency of 2% to 3% in the Western population. In 25% of MR cases, a genetic cause is suspected, of which Down syndrome and fragile X syndrome are the most common. Mutations in the *SLC6A8* gene may be, together with other X-linked MR genes, partly responsible for the skewed ratio in sex distribution in MR, autism, and individuals with learning disabilities. *SLC6A8* deficiency appears to be a relatively common cause of X-linked MR, though not as common as fragile X. Creatine biosynthesis defects may be less common. Because the damage incurred in these three diseases is irreversible to a large part and an effective treatment

is available at least for the Cr biosynthesis defects, early diagnosis of these patients is highly important.

To date, the clinical phenotype appears to be non-specific and suggests that all MR patients should be tested in diagnostic centers by ^1H -MRS, metabolite screening, and/or sequence analysis of the *SLC6A8* gene. In the case of X-linked MR or X-linked autism due to a genetic, but unknown, cause, the parents are confronted with a risk of recurrence (50% chance that the mother passes the mutant allele on to her child). The diagnosis of *SLC6A8* deficiency or a Cr biosynthesis defect allows prenatal diagnosis for subsequent pregnancies.

Creatine Supplementation/Therapeutic Use

Creatine Sources

Creatine is present in high amounts in meat (4.5 g/kg in beef, 5 g/kg in pork) and fish (10 g/kg in herring, 4.5 g/kg in salmon), which are the main exogenous Cr sources in the human diet. Low amounts of Cr can be found in milk (0.1 g/kg) and cranberries (0.02 g/kg) (17). As discussed earlier, Cr is also synthesized endogenously, which supplies around 50% of the daily requirement of approximately 2 g. This suggests that in vegetarians, who have a low intake of Cr, the bodily Cr content is reduced, unless its endogenous biosynthesis is largely increased. Indeed, in vegetarians, the Cr concentration in muscle biopsies was reported to be reduced (18).

Dosing as an Ergogenic Aid

Creatine can be obtained as nutritional supplement in the form of various over-the-counter creatine monohydrate products, which are supplied by many manufacturers. Commercial Cr is chemically produced. The majority of consumers are sportspersons, due to Cr's documented and/or presumed ergogenic and muscle mass increasing effects. Usually, a loading phase of five to seven days of 20 g/day (in four portions of 5 g) is recommended, followed by a maintenance phase with 3–5 g Cr per day.

Benefits

Benefits in Sportspersons

Creatine supplementation is common among cyclists, mountain bikers, rowers, ski jumpers and tennis, handball, football, rugby, and ice hockey players. While there is a large body of evidence supporting the ergogenic effects of Cr in high-intensity, intermittent exercise, the situation is more controversial in sports involving single bouts of high-intensity exercise, such as sprint running or swimming (2,19). In endurance exercise, there is currently no reason to believe that Cr supplementation has any benefit. There is a widespread contention that Cr supplementation, by accelerating recovery between exercise bouts, may allow more intensive training sessions. Similarly, supplementation seems to enhance recovery after injury.

In most studies, a significant weight gain has been noted upon Cr supplementation. The underlying basis for this weight gain is still not entirely clear, and may be due to stimulation of muscle protein synthesis or increased water retention. The proportion of fat tends to decrease. Most likely, the increase in body weight reflects a corresponding increase in actual muscle mass and/or volume. Therefore, it is not surprising that Cr use is popular among

bodybuilders and wrestlers. On the other hand, in mass-sensitive sports like swimming and running, weight gain due to Cr supplementation may impede the performance, or may at least counteract the ergogenic effects of Cr.

Creatine supplementation may improve muscle performance, especially during high-intensity, intermittent exercise, in four different ways by: (i) increasing PCr stores, which is the most important energy source for immediate regeneration of ATP in the first few seconds of intense exercise; (ii) accelerating PCr resynthesis during recovery periods; (iii) depressing the degradation of adenine nucleotides and possibly also the accumulation of lactate; and (iv) enhancing glycogen storage in skeletal muscle.

Benefits in Neuromuscular Disease

Besides its ergogenic effects, supplementary Cr has a neuroprotective function in several animal models of neurological disease, such as Huntington disease, Parkinson disease, and amyotrophic lateral sclerosis (ALS) (2,3,6,11). The rationale could be that these disorders, due to different causes, hamper cellular energy metabolism in the brain. In animal studies, Cr also protected against hypoxic and hypoxic-ischemic events. Therefore, Cr may be useful in the treatment of a number of diseases, for example, mitochondrial disorders, neuromuscular diseases, myopathies, and cardiopathies. Currently, the first clinical studies with Cr supplementation in neuromuscular disease are emerging. In two studies on patients with mitochondrial myopathies or other neuromuscular diseases, Tarnopolsky's group showed increased muscle strength upon Cr supplementation (11). A randomized, double-blind, placebo-controlled trial to determine the efficacy of creatine supplementation did not show a significant beneficial effect on survival and disease progression in a group of 175 ALS patients. These data are in contrast to what was suggested from animal models of ALS and tissue specimens of ALS patients (12). Studies on single subjects and small groups of neuromuscular disease patients have been reported to show both the presence and absence of beneficial effects of Cr supplementation. Recent publications on Cr supplementation in Huntington disease showed difficulty in proving the effect of Cr on the deterioration of cognitive function (20,21). In Duchenne muscular dystrophy, enhanced muscle strength upon treatment was shown; whereas, for example, in myotonic dystrophy type 2/proximal myotonic myopathy, no significant results were seen (22,23). Future studies with enough statistical power are warranted to unravel the relevance of Cr supplementation in these disorders. Clinical trials of patients with ALS, Parkinson, and other neurological diseases are currently ongoing (<http://clinicaltrials.gov/>).

Benefits in Creatine Biosynthesis Disorders

Oral supplementation with 350 mg to 2 g/kg body weight per day has been used in patients with GAMT and AGAT deficiencies. In these patients, the Cr concentration in their brains increased over a period of several months (5). In GAMT deficiency, the GAA concentration in plasma, urine, and CSF decreased with Cr supplementation, but still remained highly elevated. Guanidinoacetic acid was

found to be toxic in animals and may be partly responsible for some of the clinical signs (i.e., involuntary extrapyramidal movements). Combination therapy of Cr plus ornithine supplementation with protein (arginine) restriction reduced GAA in CSF, plasma, and urine, and almost completely suppressed epileptic seizures (7). In general, all patients with a Cr biosynthesis defect who were treated with Cr alone or in combination therapy showed improvements. Clearly, younger patients will experience the largest benefits, because less irreversible damage is to be expected. However, even older patients showed remarkable improvements (7).

Adverse Effects

Weight gain is the only consistent side effect reported. Gastrointestinal distress, muscle cramps, dehydration, and heat intolerance have been reported repeatedly. Most of these complaints may be due to water retention in muscle during the loading phase of Cr supplementation. Although a causal relationship with fluid intake has not been proven yet, subjects should take care to hydrate properly to prevent these side effects. The French Agency of Medical Security of Food (www.afssa.fr/ftp/basedoc/2000sa0086.pdf) released a statement in January 2001 that the health risk associated with oral Cr supplementation is not sufficiently evaluated, and that Cr may be a potential carcinogen. Because at present there is no scientific basis for the assertion (both Cr and Cr analogs were actually reported to display anticancer activity), this in turn has resulted in a wave of protest from suppliers and defenders of oral Cr supplementation. In fact, based on the current scientific knowledge in healthy individuals, Cr supplementation at the recommended dosages (see dosing as an ergogenic aid) should be considered safe. Unfortunately, almost nothing is known about the use of Cr in pregnancy, nor are appropriate studies in children available. Furthermore, a potential health hazard is the possible presence of contaminants in some commercial Cr preparations (see chemical synthesis).

CONCLUSIONS

Oral Cr supplementation is known or presumed to have a number of favorable effects. For example, it prevents or ameliorates clinical symptoms associated with inherited Cr biosynthesis defects, it may protect against neurological and atherosclerotic disease, (2,6) and it increases sports performance, particularly in high-intensity, intermittent exercise. Despite widespread use of Cr as an ergogenic aid and the significant public interest, the majority of studies on the properties, metabolism, and function of Cr have focused on physiological questions rather than on pharmacokinetics. As yet, the pharmacokinetics is difficult to interpret due to different (and incomplete) study designs. Currently, therefore, it is not adequately known whether Cr supplementation causes any long-term harmful effects. Some precaution is warranted based on the fact that the daily recommended dosage for ergogenic effects (i.e., 20 g during the loading phase, 3–5 g during the maintenance phase) cannot be met by normal food intake.

Dong Quai

Roy Upton

INTRODUCTION

The root of dang gui (*Angelica sinensis*; also known as dong quai; Fig. 1) is one of the primary botanicals used in traditional Chinese medicine (TCM) for the treatment of gynecological and circulatory conditions. In TCM its primary use is to both build and promote the movement of blood, and on the basis of these actions it is utilized for a myriad of conditions. Despite its widespread use among practitioners of TCM, there have been few clinical studies regarding its efficacy, although preclinical data support many of these traditional uses as well as suggest benefit for numerous other uses.

BACKGROUND

Traditional and Modern Uses

Dang gui grows at high altitudes in comparatively cold, damp, mountainous regions in China and other parts of East Asia. The plant is a fragrant perennial that has smooth purplish stems and bears umbrella-shaped clusters (umbels) of white flowers that grow to approximately 3 ft in height. Dang gui produces winged fruits in July and September. In the earliest known herbal text of China, the *Divine Husbandman's Classic of the Materia Medica* (*Shen Nong Ben Cao Jing*), dang gui is described as a herb to "supplement nature" (1). In the monumental 52-volume *Compendium of Materia Medica* (*Ben Cao Gang Mu*), written by Li Shizhen in the 16th century, dozens of uses for dang gui were elaborated. These included the following: to tonify the five major viscera, especially the heart; to generate flesh; to stop headache, back pain, menstrual pain, toothache, and pain associated with the "belt channel" (*dai mai*); to treat a wide range of skin sores and rashes; and to correct menstrual problems such as irregular menstruation, amenorrhea, and dysmenorrhea (2).

Modern research has focused on the use of dang gui for its ability to enhance circulation and oxygenation in hypoxic conditions specifically in regard to brain and cardiovascular effects. Despite the widespread popularity and use of dang gui in gynecology, there is a lack of research in modern English language journals regarding this use, though some data suggest estrogenic and both uterine relaxant and uterine stimulatory activity, depending on the fraction studied. A number of studies report on the ability of dang gui to promote the healing of tissues, specifically in ulcerative colitis and gastric ulcers, and other studies have focused on its anticancer and hepatoprotective effects, among others.

Chemistry and Preparation of Products

The primary analytes of interest in dang gui are the Z-alkylphthalides, most notably ligustilide (Fig. 2), low- and high-molecular-weight polysaccharides, and ferulic acid (Fig. 2). The alkylphthalides are present in the essential oil and are strongly aromatic. Both the crude extract and individual compounds have been correlated with biological activity (see preclinical studies; clinical studies). The crude extract has been associated with positive human clinical effects for the treatment of chronic obstructive pulmonary disease (COPD) and COPD with hypertension, increasing blood volume in postischemic patients, and decreasing platelet aggregation (3). The alkylphthalides and ferulic acid inhibit platelet aggregation and the formation of platelet thromboxane A_2 (4–6) and elicit in vitro spasmolytic activity, increase coronary blood flow, slightly decrease myocardial contractility, and markedly prolong the effective refractory period (7). Total extracts have also been associated with hepatoprotective effects. Thus dang gui is utilized in portal hypertension and veno-occlusive disease. At least part of this activity is associated with the demonstrated antioxidant activity of ligustilide, ferulic acid, and polysaccharides (8–10), as well as the ability of dang gui to promote hepatic microcirculation. In human clinical trials both an aqueous extract and ligustilide have been found to be effective in treating dysmenorrhea (11). Dang gui polysaccharides stimulate hematopoiesis and, along with ferulic acid, elicit immunomodulatory activity (e.g., increased phagocytosis) (12,13). Ligustilide and ferulic acid elicit a strong uterine spasmolytic effect (14–17). All of these actions are consistent with the use of dang gui in traditional Chinese medicine.

Investigations of polysaccharides derived from dang gui, specifically in conjunction with their potential immunomodulatory effects have been conducted. The polysaccharides, named *A. sinensis* polysaccharide fractions (APF 1, APF 2, APF 3) and crude angelica polysaccharide consist of rhamnose, galacturonic acid, glucose, galactose, mannose, and arabinose in various ratios (18,19).

In TCM, the roots of dang gui are commonly prepared as a tea, extract, syrup, tablet, or capsule. In supplement form, dang gui occurs predominantly in tablets and capsules, and occasionally in tinctures. As with the majority of Chinese herbs, dang gui is most often used in combination with other botanicals and is predominantly featured in formulas for promoting healthy gynecological and cardiovascular systems and for a healthy liver. Different portions of the roots are used for different indications. The whole roots are said to "harmonize" the

Figure 1 Whole dang gui (*Angelica sinensis*) roots. Source: Courtesy of Roy Upton, Soquel, California. (View this figure in color at www.dekker.com)

blood; the dang gui root bodies (dang gui tou; 当归头) are used to build and nourish the blood and are commonly included in soups for convalescence and blood deficiency; the tails (dang gui wei; 当归尾) are predominantly used to “break the blood” and prevent and treat abnormal blood stagnation.

Pharmacokinetics

There are limited data on the pharmacokinetics of some of the compounds contained within dang gui. In a study of the bioavailability of ferulic acid in humans ($n = 5$), the peak time for maximal urinary excretion of ferulic acid following the consumption of 360 to 728 g tomatoes (providing approximately 21 to 44 mg ferulic acid) was 7 to 9 hours (20). A considerable proportion of ferulic acid was excreted as glucuronide in all subjects. The recovery of ferulic acid in the urine, on the basis of total free ferulic acid and feruloyl glucuronide excreted, was 11% to 25% of that ingested. The bioavailability of ferulic acid from beer is consistent with the uptake of ferulic acid from other dietary sources, such as tomatoes (21). Urinary and biliary metabolites of ferulic acid were primarily glucuronic acid and glycine conjugates of ferulic acid and vanillic acid (22).

The pharmacokinetic parameters of ferulic acid following IV injection to mice fit a one-compartment open

model and suggest that ferulic acid is rapidly and almost completely absorbed from the intestinal tract (23). It has also been reported that ferulic acid crosses the blood–brain barrier, although in very low concentrations (24). The major metabolites of ferulic acid are nontoxic and water soluble, being excreted through the urine and bile as free acids and acid conjugates.

PRECLINICAL STUDIES

Pharmacodynamics

Dang gui is one of the most widely used of all Chinese botanicals. Historically and in modern Chinese medicine, it has been primarily used as a general blood tonic for the TCM diagnosis of blood deficiency, a syndrome closely related, but not exactly analogous or limited, to anemia. Dang gui has also been used for a myriad of gynecological indications, although there has been very little research done in this regard in English language journals. More recently, pharmacological research has focused on the potential of constituents of dang gui to elicit cardiovascular, hematopoietic, hepatoprotective, antioxidant, antispasmodic, and immunomodulatory effects. Chinese botanicals are most often used in multi-ingredient formulas rather than as single agents. Therefore, there are very few clinical trials on dang gui alone, although numerous preclinical studies exist. Due to the lack of primary English language literature, it is difficult to adequately access or adequately review the available data by non-Chinese language readers. Another difficulty in reviewing the available studies is that many of the investigations are of disease patterns that are unique to TCM and do not have well-defined corresponding Western diagnoses, or vice-versa; studies are conducted for indications not synonymous with TCM indications. While the TCM findings are relevant to TCM practitioners, their importance may be ignored or even criticized by non-TCM practitioners. Study of non-TCM indications often is conducted for purposes of modern drug discovery and therefore can be criticized on different grounds. Lastly, it has been reported that up to 99% of studies presented in the Chinese medical literature show results favoring test intervention, suggesting the potential for a positive publication bias and hence the need for caution in interpreting the available data (25). Conversely, publication bias against dietary supplement research in the primary medical literature of the United States has been reported and may similarly limit a critical review of investigations of herbal products (26).

The bioactive compounds most studied in dang gui are phthalides, polysaccharides, and ferulic acid. Studies using these compounds have reported a number of therapeutic effects, some of which are consistent with the use of dang gui in TCM and some of which are not. The contribution of ferulic acid to the therapeutic effect of dang gui is unlikely given its low concentration in crude dang gui (0.05–0.09%). The compounds used in pharmacological studies are often administered at doses exceeding those available from typical dosages of dang gui root preparations. While these data are presented, it is not possible to extrapolate results from such studies to clinical efficacy of orally administered crude drug products; hence, the reported findings must be evaluated critically.

Figure 2 Major constituents of dang gui.

Cardiovascular and Hemorheological Effects

Clinically, dang gui is widely used for the treatment of cardiovascular disease, specifically conditions that can benefit from enhanced circulation and a decrease in platelet aggregation. Preclinical studies using dang gui and some of its constituents suggest actions and mechanisms by which it may exert a cardiovascular effect. These include stimulation of circulation, platelet aggregation inhibition, decrease in myocardial oxygen consumption, and vasorelaxation (measured as a decrease in vascular resistance; see also effects on smooth muscle).

A number of animal studies and in vitro assays support some of the putative cardiovascular effects of dang gui. These include an increase in myocardial perfusion, decrease in myocardial oxygen consumption, increase in blood flow, decrease in vascular resistance, and inhibition of platelet aggregation, ventricular fibrillation, and arrhythmias (3). However, a direct extrapolation of these findings to humans cannot be made without confirmatory human studies. A review of the activity of sodium ferulate reported that it both inhibits platelet aggregation and elicits a thrombolytic activity in vitro and in vivo. These effects were due to inhibition of cyclooxygenase and thromboxane A₂ synthase with improvements in blood viscosity, reduction in the concentration of plasma fibrinogen, and increase in coronary perfusion. Additional cardiovascular effects reported include reduction of cholesterol biosynthesis and lowering of triglycerides, improvements in myocardial oxygen consumption, and antiarrhythmic, antioxidant, and antiatherogenic activity (24).

Hepatoprotective Effects

A number of preclinical studies indicate that dang gui, dang gui polysaccharides, ferulic acid, and sodium ferulate have antioxidant effects that can protect the liver against damage due to chemically induced toxicity. Part of this action is due to the ability of dang gui polysaccharides to reduce the levels of nitric oxide (24.6%), serum alanine aminotransferase (40.8%), and serum glutathione S-transferase (18.4%) in animals with acetaminophen-induced or carbon tetrachloride-induced liver damage (8,9,27,28).

Gynecological Effects

Dang gui is one of the most important herbal medicines in TCM for the treatment of menstrual disorders, especially when used in combination with other botanicals. It has traditionally been used to treat conditions associated with the TCM diagnosis of "blood stasis" and "blood vacuity," which can be correlated with Western syndromes such as amenorrhea, dysmenorrhea, endometriosis, uterine fibroids, and certain forms of infertility. Its efficacy appears to have been demonstrated over the 750-year history of its use for these indications and its continued, and apparent, successful use by modern practitioners of TCM. However, there are few studies substantiating these effects (11,29), and those that are available lack methodological rigor.

Using ELISA-type immunoassays of two steroid-regulated proteins, presenilin-2 and prostate-specific antigen, in breast carcinoma cell line BT-474, researchers reported that dang gui extract showed "weak" estrogen and androgen antagonistic effects of 50% and 71% blocking activity, respectively, and no progestational activity (29). In

contrast to these findings, another group of researchers found no estrogen receptor binding, cell proliferation, or progestin activity of an aqueous-ethanol extract of dang gui (30).

A study of ovariectomized rats showed that an extract of dang gui (300 mg/kg SC; 1% ligustilide) resulted in a thickening of the luminal epithelium suggesting an estrogenic activity, but one much lower than comparison with estradiol. The extract also suppressed luteinizing hormone secretion. The researchers considered ligustilide to be the active compound on the basis of previous in vitro research they conducted (31). Several preclinical studies have investigated the estrogenicity of dang gui or ferulic acid, with mixed, but largely negative, results. Some in vitro assays have reported that dang gui extract exhibited a significant dose-dependent inhibition of estrogen receptor binding, indicating that it competed with estradiol for receptor sites (32). In the same study, dang gui extract dose-dependently induced reporter gene expression in estrogen-sensitive rat uterine leiomyoma cells, suggesting a potentially proliferative effect on these cells. However, when tested in conjunction with the maximum stimulatory dose of estradiol, the extract inhibited estradiol-induced reporter gene expression, suggesting the possibility that dang gui may act as an estrogen antagonist when in the presence of physiological levels of estradiol. Another group of researchers reported similar findings (33).

Effects on Smooth Muscle

Dang gui and its constituents have been shown to relax the smooth muscle tissue of the vascular system, trachea, intestines, and uterus. The spasmolytic effects of dang gui on trachea and uterine tissues are consistent with TCM indications. While the mechanism of the relaxant action has not been fully elucidated, preclinical studies suggest that it may be due, in part, to histamine receptor blocking activity, calcium ion channel effects, or modulation of cholinergic receptors. Both relaxing and stimulating effects on uterine tissue have been reported, with various constituents eliciting different actions. The therapeutic relevance of in vitro findings to humans is unknown given the lack of clinical evidence. Ex vivo studies demonstrate that ligustilide and butylidenephthalide isolated from the volatile oil of dang gui exhibit a strong spasmolytic effect on isolated uteri (34,35). Ligustilide was shown to relax early pregnant and nonpregnant uteri of experimental animals (34). Ligustilide and butylidenephthalide showed an inhibitory effect on prostaglandin F₂-, oxytocin-, or acetylcholine-induced contraction of nonpregnant rat uteri (14,36). This could explain the spasmolytic effect of the volatile oil. Other studies indicated that the observed spasmolytic effect may be due to an effect on calcium channels (14,37). Three of the available studies reviewed found that ferulic acid elicited a uterine spasmolytic effect. At oral doses of 300 to 1000 mg/kg and IV doses of 30 to 300 mg/kg, ferulic acid inhibited spontaneous uterine contraction in rats (16,17). The inhibitory effect of IV ferulic acid was not blocked by either propranolol or by cimetidine and it strongly inhibited the uterine contraction induced by oxytocin (0.3 unit/kg), but not that induced by acetylcholine (0.1 mg/kg) or serotonin (10 µg/kg). It was suggested that the uterine relaxant effect of ferulic acid is partially due to the oxytocin receptor

system rather than its inhibitory effect on prostaglandin biosynthesis (38). Another study, however, suggested that ferulic acid may not be responsible for the spasmolytic effect of dang gui, since its content in raw material is low (approximately 0.03% to 0.06%) (39).

Hematopoietic Effects

One of the traditional applications of dang gui in TCM is its use in the treatment of "blood vacuity," which closely, but not completely, corresponds to a Western medical diagnosis of anemia. Limited clinical and preclinical data support this use. One proposed mechanism of action is its reported effect in stimulating hematopoiesis. These actions appear to be primarily associated with the polysaccharide fraction (13,40). One study demonstrated the hematopoietic effects to at least partially be associated with proliferation of bone marrow mononuclear cells through signal transduction pathways (e.g., MAPK/ERK pathway) (41).

Antioxidant Effects

There have been numerous studies demonstrating an antioxidant effect of dang gui and its constituents. Much of these have focused on the antioxidant activity of ferulic acid, which is well known for its ability to prevent lipid peroxidation, inhibit superoxide anion radical formation, scavenge free radicals, and protect against radiation damage (42–44). Dang gui contains only trace amounts of ferulic acid, so these in vitro findings cannot be extrapolated to the use of crude dang gui preparations. There are, however, animal studies showing that dang gui polysaccharides have a protective effect against chemically induced ulcerative colitis and inflammation. In one study, dang gui polysaccharides elicited anti-inflammatory effects in the gastrointestinal mucosa through inhibition of neutrophil infiltration in the stomach (45). In another study, dang gui polysaccharides (5 mg and 10 mg/mL in drinking water) attenuated colonic lesions caused by oxidative damage induced by 2,4-dinitrobenzene sulfonic acid in rats in a dose-dependent manner. This action was associated with a preservation of endogenous glutathione levels. Other studies reported tissue-healing effects of dang gui to be associated with ornithine carboxylase activity, c-Myc protein expression, and epidermal growth factor-mediated pathway (27,46). A follow-up study by the same group of researchers showed that crude extract of dang gui (50 mg/kg PO) significantly accelerated the healing of gastric ulcers in animals and showed an anti-angiogenic activity and a quicker restoration of mucosal synthesis and mucosal cell proliferation (47).

Studies suggest that the antioxidant activity of dang gui may reduce ischemia-reperfusion induced injury (48,49), ameliorate cognitive dysfunction associated with postischemic brain damage (49), and inhibit the damage associated with aggregation of amyloid- β peptide, suggesting a possible use of dang gui in Alzheimer's. These effects were reported to be correlated with both ferulic acid and Z-ligustilide (50).

Other studies show that dang gui provides antioxidant protection against free radical induction of rat adrenal medulla (PC12) cell lines (51) and suppressed radiation-induced expression of tumor necrosis factor- α and tumor growth factor- β -1 (52), and prevented

doxorubicin-induced cardiotoxicity, without decreasing the antitumor activity of the drug (53).

Wound-Healing Effects

In addition to the beneficial effects of dang gui's antioxidant activity on tissues noted earlier, specific wound-healing properties have been reported. One group of researchers found that a crude extract of dang gui (characterization and dosage not available) significantly accelerated epithelial cell proliferation in wounds (27,46,54). The activity was reportedly associated with an increase in DNA synthesis and epidermal growth factor mRNA expression. The same researchers observed direct wound-healing effects of dang gui crude extract, with activity associated with increased ornithine carboxylase activity and increased c-Myc expression. Another study found that dang gui prevented bleomycin-induced acute injury to rat lungs. Alveolitis and the production of malondialdehyde were all reduced ($P < 0.01$ or $P < 0.001$), suggesting immunomodulatory and antioxidant effects (55).

Immunomodulatory Effects and Potential Anticancer Activity

Limited animal and in vitro studies have reported on specific immunomodulatory effects of dang gui, including stimulation of phagocytic activity and interleukin-2 production, and an anti-inflammatory effect. There is evidence to suggest that the polysaccharide fraction of dang gui may contribute to these effects. However, there is no clinical evidence supporting these effects, and there appears to be no direct correlation between TCM use of dang gui and immunomodulatory activity (56–58).

A new direction in investigation of the use of dang gui is for its potential anticancer activity. Ligustilide has been shown to have direct cytotoxic activity against several human and animal cell lines (59–61). In the absence of clinical and directly applicable toxicological investigation, little emphasis should be placed on these in vitro findings. There have, however, been a number of animal studies suggesting immunomodulatory and anticancer activity. In one study, *n*-butyridenephthalide suppressed growth of subcutaneous rat and human brain tumors, reduced tumor volume, and significantly prolonged survival in treated rats. This activity was reported to be due to an induction of cell cycle arrest and apoptosis (62). Polysaccharides have similarly been shown to inhibit growth of murine tumors (S180, EAC, L1210) in vivo, resulting in a prolonged survival of treated animals. In vitro, dang gui polysaccharides were shown to inhibit the metastasis of human hepatocellular cancer cell lines (63).

A variety of immunomodulatory activities have been reported for dang gui polysaccharides, including enhanced macrophage and T cell numbers, increased production of interleukin and interferon, improved CD4/CD8 ratios, and a general regulation of Th1- and Th2-related cytokines (18). Other actions reported for polysaccharides include release of nitric oxide from peritoneal macrophages and enhanced cellular lysosomal enzyme activity (64,65).

Effects on Bone Cells

Dang gui is traditionally used in formulas for bone and tendon injuries. A recent study investigated the

pharmacology behind this indication by testing the *in vitro* effects of a 1% aqueous extract of dang gui on human osteoprecursor cells. Cells were incubated for five days in medium with (12.5–1000 $\mu\text{g/mL}$) and without the extract. Compared to untreated control cell cultures, cell proliferation was enhanced at extract concentrations less than 125 $\mu\text{g/mL}$ ($P < 0.05$), whereas it was inhibited at concentrations greater than 250 $\mu\text{g/mL}$ ($P < 0.05$ at 1 mg/mL). Protein secretion in osteoprecursor cells and type-I collagen synthesis were significantly increased ($P < 0.05$) (66).

CLINICAL STUDIES

The clinical data regarding the use of dang gui alone are scarce and of poor methodological quality.

Cardiovascular and Hemorheological Effects

One study reported that 0.08 g/day/IV of sodium ferulate relieved symptoms of angina pectoris after three to seven days of treatment (24). Limited clinical studies have investigated the use of dang gui for the treatment of patients with acute ischemic stroke or COPD with pulmonary hypertension. Results provide fairly weak evidence that dang gui exerts hypotensive and cardioprotective effects. In general, the study design of the available reports was poor and the patient populations extremely limited.

One study looked at the effects of dang gui in 60 patients with COPD (67). In the dang gui group, levels of blood endothelin-1, angiotensin II, endogenous digitalis-like factor, mean pulmonary arterial pressure, and pulmonary vascular resistance were decreased significantly ($P < 0.05$ or $P < 0.01$) compared to those in the controls ($20 \pm 6\%$, $36 \pm 9\%$, $38 \pm 11\%$, $17 \pm 5\%$, and $27 \pm 8\%$, respectively). Another study showed that dang gui decreased the mean pulmonary arterial pressure in patients with COPD without changing blood pressure and heart rate, suggesting a vasodilatory effect on pulmonary vessels without effect on systemic circulation (3).

In another study, it was suggested that dang gui and dextran exhibited positive effects on neurological and hemorheological symptoms in patients recovering from stroke (68). However, no control group was included, and so any claimed effects are questionable. Other clinical studies with very small numbers of patients (11,69) have reported on an ability of dang gui to decrease blood viscosity, an effect consistent with its traditional use. While this effect may be real, the mechanisms by which this may occur and the constituents involved have not been well articulated.

Hepatoprotective Effects

There is some evidence to suggest that dang gui and its constituents can decrease portal hypertension in patients with liver cirrhosis without affecting systemic hemodynamics. This use is consistent with the traditional actions of dang gui in improving circulation, because portal hypertension is thought to be due to the obstruction of hepatic microcirculation (70,71).

Hormonal Effects and Effects on Menopausal Symptoms

Because of the putative effects of dang gui in gynecological imbalances, various studies have investigated its potential for eliciting hormonal effects. In one human study (72), one of the few double-blind, placebo-controlled trials with dang gui, no statistically significant differences in endometrial thickness, vaginal cell maturation, or menopausal symptoms were observed between subjects taking dang gui and those taking placebo. This contrasts with a study of ovariectomized rats which showed that an extract of dang gui (300 mg/kg SC ; 1% ligustilide) resulted in a thickening of the luminal epithelium suggesting estrogenic activity, but one much lower than comparison with estradiol (see gynecological effects).

Analgesic Effects

Two uncontrolled clinical trials were found that addressed the traditional Chinese use of dang gui as an analgesic for pain due to "blood stasis"; both used injectable preparations. In one, an ethanol extract was administered (intramuscularly) on alternate days for a total of 20 doses into the pterygoideus externus of 50 patients with temporomandibular joint syndrome. A 90% cure rate was claimed (73). Thirty cases of refractory interspinous ligament injury were treated by local injection of 2 mL of 5% or 10% dang gui twice weekly for two to three weeks. Twenty-four (80%) of these patients reported a disappearance of pain, no tenderness, and the ability to work as usual; four (13%) patients reported alleviation of pain; two (7%) reported no improvement (74). These uses are consistent with the traditional use of dang gui in TCM. However, the effects of injectable preparations cannot be extrapolated to oral use of dang gui.

Dosages

- Crude herb: 6 to 12 g daily to be prepared as a decoction.
- Fluid extract (1:1): 3 to 5 mL three times daily (75).

SAFETY PROFILE

Side Effects

On the basis of a review of the available traditional and scientific data, dang gui is a very safe herb with a low probability of side effects when used within its normal dosage range. One review article that claimed to cover 200 reports on dang gui pharmacology stated that dang gui had no major side effects (35). Individual case reports regarding the potential of dang gui to promote bleeding have been prepared.

Contraindications

On the basis of a review of the available literature and the experience of practitioners, dang gui is contraindicated prior to surgery and, generally speaking, in those with bleeding disorders.

Precautions

Precautions regarding the use of dang gui and other botanicals used in traditional systems of medicine must be differentiated between those recognized in the scientific literature and those recognized traditionally. There is evidence suggesting an anticoagulant effect for dang gui, and there

are two published reports on its ability to enhance the effects of chronic treatment with warfarin (see interactions). A few unpublished case reports suggest that high doses or chronic administration of dang gui alone during pregnancy may be associated with miscarriage. There are also anecdotal reports of administration of dang gui alone causing increased blood flow during menses (R.U., personal communication). Therefore, patients should consult with a qualified health care professional prior to using dang gui if they have bleeding disorders, are using anticoagulant medications, or wish to use it during menses or in the first trimester of pregnancy. It must, however, be noted that in TCM, dang gui is specifically indicated for certain bleeding disorders that are due to an underlying diagnosis of blood stasis and in certain cases of threatened miscarriage. For such uses, dang gui must be used according to TCM principles under the guidance of a qualified TCM practitioner.

Interactions

Two reports are available suggesting that dang gui can enhance the effects of the anticoagulant warfarin. According to one of these, a 46-year-old woman with atrial fibrillation who had been stabilized on warfarin for almost two years (5 mg daily) consumed a dang gui product concurrently for four weeks (565–1130 mg daily). She experienced a greater than twofold elevation in prothrombin time (from 16.2 to 27 sec) and international normalized ratio (from 2.3 to 4.9). No other cause for this increase could be determined. Within one month of discontinuing dang gui use, coagulation values returned to acceptable levels (76).

An animal study investigated the interaction of dang gui and a single dose or a steady-state dose of warfarin (77). Six rabbits were administered a single dose of warfarin (2 mg/kg SC). Seven days later, the same animals were given an aqueous extract of dang gui (2 g/kg PO, twice of a 2 g/mL extract daily) for three days, after which they were again given a single dose of warfarin. Plasma warfarin concentrations were measured at intervals up to 72 hour after each warfarin dose, and prothrombin time was measured daily during dang gui treatment and after the warfarin doses. Mean prothrombin time did not change significantly during the dang gui treatment period. However, when measured after coadministration of dang gui and warfarin, prothrombin time was significantly lowered at 24, 36, and 48 hours compared to that with warfarin treatment alone ($P < 0.05$ or $P < 0.01$). No significant variations in the single dose pharmacokinetic parameters of warfarin were observed after treatment with dang gui. Hence, the mechanism of decrease in prothrombin time could not be correlated to the pharmacokinetics of warfarin. Another group of six rabbits was given 0.6 mg/kg of warfarin SC daily for seven days; a steady-state plasma concentration was achieved after day 4. On days 4, 5, and 6, the rabbits were treated as above with dang gui. Mean prothrombin time was again significantly increased after coadministration with dang gui and two rabbits died at days 6 and 7 after the dang gui treatment had begun. Plasma warfarin levels did not change after dang gui treatment. The authors suggested that these results indicate that precautionary advice should be given to patients who medicate with dang gui or its prod-

ucts while on chronic treatment with warfarin. Another study reported that dang gui acted synergistically with aspirin (24).

General enhancement of cytochrome P450 isoforms has been reported for both water (CYP2D6 AND 3A) and ethanol extracts (CYP2D6) of dang gui in animal models (78).

One study reported that dang gui might enhance the antitumor effect of cyclophosphamide in mice with transplanted tumors (79).

Pregnancy, Mutagenicity, and Reproductive Toxicity

Because of its blood-moving properties, dang gui should be used in pregnancy only under the supervised care of a qualified health professional. According to TCM practice, dang gui is used in combination with other herbs in various stages of pregnancy (29). Formula traditionally used in pregnancy are prescribed within the context of specific diagnoses in which the use of dang gui in pregnancy is clearly indicated. In the West, dang gui is often used alone out of this traditional medical context. Because of this, several Western sources consider dang gui to be contraindicated in pregnancy. Data regarding the effect of dang gui preparations on the fetus are lacking.

Lactation

There are three unpublished case reports of a rash in infants of lactating mothers who were taking dang gui. The rashes reportedly resolved upon discontinuation of the preparation by the mother. Specific details regarding the preparations used were lacking (Romm, August 1, 2002, oral communication to AHP). Dang gui is a member of the botanical family Apiaceae, a group of plants that contain many types of photoreactive compounds known to cause rashes.

Carcinogenicity

Data regarding the effects of dang gui in relationship to carcinogenicity are mixed with both tumorigenic and antitumorigenic activity reported. Antitumor activity due to an induction of cell cycle arrest and apoptosis has been reported for ligustilide (62). Polysaccharides have been shown to inhibit growth of murine tumors (S180, EAC, L1210) in vivo. This was accompanied by a prolonged survival of animals and an inhibition of metastasis in vitro (63). Another animal study identified a possible antitumor effect of dang gui applied to mice with Ehrlich ascites tumors (80). Regarding the potential effects of dang gui on estrogen-positive tumors the data are mixed. One in vitro assay found that dang gui stimulated the growth of MCF-7 breast cancer cell lines 16-fold, with no measurable effect on estrogen receptors (81), while another found a possible antitumor effect in T-47D and MCF-7 cell lines (82). Data regarding the potential estrogenic effects of dang gui have been mixed.

Influence on Driving

On the basis of the experience of modern herbal practitioners, no negative effects are to be expected.

Overdose

On the basis of the available literature, its use as a "food" ingredient in soups, and the experience of modern herbal

practitioners, dang gui appears to be safe when used at recommended doses.

Treatment of Overdose

No data available.

Toxicology

The following lethal dose (LD₅₀) values have been reported for dang gui extract (8:1 or 16:1), 100 g/kg PO in rats (83,84); dang gui aqueous extract, 100 g/kg IV in mice (85); dang gui 50% ethanol extract, greater than 40 g/kg PO in mice (86); dang gui total acids, 1.05 ± 0.49 g/kg IP in mice (87). The LD₅₀ of ferulic acid IV in mice was reported to be 856.6 mg/kg, (16) and that of ligustilide, approximately 410 mg/kg IP (88). In a review of the toxicology literature on dang gui, it was reported that IV injection of the volatile fraction of dang gui could cause kidney degeneration (76).

REGULATORY STATUS

Regulated as a dietary supplement (USC 1994).

CONCLUSIONS

Dang gui is one of the most important herbal drugs in TCM, primarily being used for blood tonification and the treatment of gynecological disorders. More recently, interest has focused on dang gui's possible cardiovascular, hepatoprotective, hematopoietic, antioxidant, antispasmodic, and immunomodulatory effects. Despite its long tradition of use and current widespread clinical utility, there has been very little clinical work verifying the therapeutic efficacy of dang gui when used alone, primarily due to the fact that in TCM, botanicals are generally used in combinations rather than as single agents.

On the basis of the literature available and keeping many of its limitations for an English readership in mind, there is limited clinical support for the use of dang gui alone for the following indications: pulmonary artery and portal hypertension, acute ischemic stroke, dysmenorrhea, infertility, and pain due to injury or trauma. The use of dang gui for most of these indications is consistent with TCM. One trial on menopausal symptoms found no effect of dang gui on hormonal activity. Most of the trials available are of poor methodological quality.

Clinical and preclinical studies provide some support for a wide variety of actions of dang gui. These include the promotion of circulation, vasodilation/relaxation, and the inhibition of platelet aggregation, all of which are consistent with the "blood quickening" properties ascribed to dang gui in TCM. Similarly, the hematopoietic effect of dang gui is consistent with its use in TCM to "nourish blood." Its smooth muscle (uterus, vessels, trachea) relaxant effects are consistent with its use for dysmenorrhea, asthma, and coughing. Dang gui may relax or stimulate the uterus depending on a variety of factors. In general, the volatile oil fraction appears to be a uterine relaxant, while the nonvolatile constituents appear to stimulate contractions. There is some support for the traditional use of dang gui as an analgesic and vulnerary. The radiation protective effect of dang gui in animals

is most likely due to its antioxidant activity. Assays for an estrogenic effect of dang gui have had mixed, but largely negative, results. The relevance of many of these actions to the therapeutic use of dang gui in humans has not yet been demonstrated.

Dehydroepiandrosterone

Salvatore Alesci, Irini Manoli, and Marc R. Blackman

INTRODUCTION

DHEA is the acronym used to designate the hormone “dehydroepiandrosterone,” also referred to as “prasterone.” The chemical name for DHEA is 5-androsten-3 β -ol-17-one (Fig. 1).

DHEA is available as an over-the-counter dietary supplement in the United States, as the Food and Drug Administration did not include it in the 2004 Anabolic Steroid Control Act, which reclassified other related agents as anabolic steroids and hence, controlled substances. As a dietary supplement, it is marketed under different trade names (e.g., Nature’s Blend DHEA, Nature’s Bounty DHEA, DHEA Max, DHEA Fuel, etc.). A pharmaceutical-grade preparation, currently available only for experimental use, has been assigned the trade name Prestara (previously known as Aslera or GL701).

HISTORICAL OVERVIEW AND GENERAL DESCRIPTION

Discovered in 1934, DHEA is the most abundant steroid hormone, and is produced by the adrenal glands in humans and other primates. It acts as a weak androgen and serves as a precursor of other steroids including more potent androgens and estrogens. To date, however, the exact functions of this hormone remain unknown. DHEA is broadly traded on the Internet, under the claim of being a “marvel hormone.” Despite the growing popularity of its use, there is insufficient scientific evidence supporting the purported potential health benefits, and little information regarding the potential short- and long-term adverse risks of consuming exogenous DHEA. Moreover, variations in quality control and manufacturing practices of dietary supplements result in differences in concentrations and purity of the marketed compounds, and insufficient surveillance for side effects.

BIOCHEMISTRY AND PHYSIOLOGY

Biosynthesis and Metabolism

DHEA is primarily produced in the zona reticularis of the adrenal cortex. In healthy women, the adrenal gland is the principal source of this steroid, whereas in men, 10% to 25% of the circulating DHEA is secreted by the testes (1). It can also be synthesized within the central nervous system (CNS), and can be considered a “neurosteroid” (2). Pregnenolone, the immediate precursor of

DHEA, is derived from cholesterol through the action of the cytochrome P450 side-chain cleavage enzyme (CYP-scc). It is converted into DHEA by cytochrome P450 17 α -hydroxylase (CYP17), while hydroxysteroid sulfotransferase (DHEAST) catalyzes the transformation of DHEA into its 3-sulfated metabolite DHEAS (Fig. 2). This can be converted back to DHEA by the action of sulfohydrolases (DHEASH), located in the adrenal gland and peripheral tissues.

Human plasma contains DHEA-fatty esters (DHEA-FA), which are formed from DHEA by the enzyme lecithin-cholesterol acyltransferase. Newly formed DHEA-FA are incorporated into very low-density lipoproteins (VLDL) and low-density lipoproteins (LDL) and may be used as substrates for the synthesis of active oxidized and hydroxylated metabolites in the periphery, such as 7 α / β -hydroxy-DHEA in the brain, and androstenedione, androstenediol, and androstenetriol in the skin and immune organs (3,4).

Regulation of DHEA Production

Release of DHEA by the adrenals is mostly synchronous with that of cortisol, under the stimulus of the hypothalamic corticotrophic-releasing hormone (CRH) and pituitary adrenocorticotrophic hormone (ACTH). However, the finding of dissociation between DHEA and cortisol secretion during several physiologic and pathophysiologic states suggests that other non-ACTH-mediated mechanisms may be involved in the modulation of DHEA secretion (Table 1).

Estrogens, growth hormone, insulin, and prolactin stimulate DHEA secretion by human adrenal cells. However, these findings have not always been replicated in animal or clinical studies. A complex intra-adrenal network involving vascular and nervous systems, local growth and immune factors, and a “cross talk” between cells of the cortex and medulla, the other component of the adrenal gland, also regulate DHEA secretion. The existence of a specific “adrenal androgen-stimulating hormone” has also been postulated, but remains controversial (5).

Adrenarche and Adrenopause

At birth, DHEAS is the predominant circulating steroid. However, a dramatic involution of the fetal adrenal zone, starting in the first postnatal month and continuing through the first year of life, is paralleled by a sudden decrease in DHEA/DHEAS, which remains unchanged for the next six years. By the age of six to eight years, the adrenal gland matures, culminating in the creation of

Figure 1 Chemical structure of dehydroepiandrosterone (DHEA).

the zona reticularis, followed by an abrupt elevation in DHEA and DHEAS concentrations, termed the “adrenarche” (6). Peak concentrations of DHEA (180–800 ng/dL) and DHEAS (45–450 μ g/dL) are reached during the third decade of life. Subsequently, there is a progressive 2% decline per year in DHEA and DHEAS secretion and excretion, with concentrations equal to 20% of the peak by the age of 80, and values lower in women than in men (5,7). This marked decline has been termed “adrenopause.” DHEA and DHEAS levels are higher in men than in women at all ages.

Mechanisms of Action

Despite the identification of high-affinity binding sites for DHEA in rat liver, T-lymphocytes, and endothelial cells, the search for a specific, cognate DHEA receptor has been unsuccessful. Multiple mechanisms of action have been proposed for DHEA. Most important among these are that DHEA can be metabolized into more potent androgens [testosterone and dihydrotestosterone (T and DHT)] and estrogens (estradiol and estrone) in the periphery, which

Table 1 Dissociation of Cortisol and DHEA/DHEAS Secretion During Physiological and Pathological Conditions

Condition	DHEA	DHEAS	Cortisol

can interact with specific androgen and estrogen receptors. DHEA itself can bind to the androgen and estrogen receptors, but its affinity is extremely low compared with those of the native ligands. It has been estimated that DHEA and DHEAS function as precursors of 50% of androgens in men, 75% of active estrogens in premenopausal women, and 100% of active estrogens in postmenopausal women (8). Lipophilic DHEA, but not hydrophobic DHEAS, can be converted into both androgens and estrogens intracellularly in target tissues by “intracrine” processes (4). This conversion depends on the levels of different steroidogenic and metabolizing enzymes, and on the hormonal milieu. For example, DHEAS and sulfatase are present in high concentrations in the prostate, and the resultant metabolism of DHEA to DHT accounts for up to one-sixth of the intraprostatic DHT (9).

DHEA can also function as a neurosteroid, by modulating neuronal growth, development, and excitability, the latter via interaction with γ -aminobutyric acid ($GABA_A$), *N*-methyl-D-aspartate (NMDA), and sigma receptors (10). It is known to be a potent inhibitor of glucose-6-phosphate dehydrogenase (G6DPH), thus interfering with the formation of mitochondrial nicotinamide adenine dinucleotide phosphate [NADP(H)] and ribose-6-phosphate and inhibiting DNA synthesis and cell proliferation (11). The steroid hormone has also been proposed to exert antigluccorticoid, cytokine modulatory, potassium channel and cyclic guanylyl monophosphate (cGMP) stimulatory, and thermogenic effects.

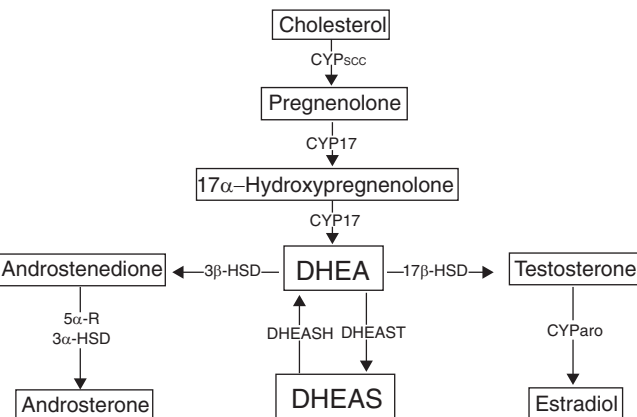

Figure 2 Schematic diagram of DHEA/DHEAS biosynthesis and metabolism. Abbreviations: CYPsc, cytochrome P450 side-chain cleavage enzyme; CYP17, cytochrome P450 17 α -hydroxylase; 3 β /17 β /3 α -HSD, 3- β /17- β /3 α hydroxysteroid dehydrogenase; 5 α -R, 5- α reductase; DHEASH, DHEA sulfohydrolase; DHEAST, DHEA sulfotransferase; CYParo, cytochrome P450 aromatase.

PHARMACOKINETICS

Absorption and Tissue Distribution

While DHEA is marketed as an oral product, it has also been shown to be absorbed when administered by the transdermal, intravenous, subcutaneous, and vaginal

routes. Crystalline and micronized formulations result in higher DHEAS serum concentrations, possibly due to an enhanced rate of absorption (12). After absorption in the small intestine, DHEA is mainly sulfated in the liver. The nonoral route averts first pass liver degradation, resulting in higher serum levels. DHEA concentrations are high in the brain, with a brain-to-plasma ratio of 4–6.5:1 (13) and plasma, spleen, kidney, and liver concentrations follow in descending order. Cerebrospinal, salivary, and joint fluid levels are directly related to those of serum.

Bioavailability, Metabolism, and Clearance

Pharmacokinetic studies on DHEA reveal a clearance rate compatible with a two-compartment model. The initial volume of distribution is 17.0 ± 3 L. DHEA disappears from the first compartment in 17.2 ± 6.2 minutes and from the second in 60.2 ± 12.3 minutes (14). DHEAS follows a one-compartment model of disappearance. Its volume of distribution is 4.6 ± 0.9 L, while the half-life from that compartment is 13.7 hours (15). In men, 77.8 \pm 17.3% of the DHEAS that enters the circulation will reappear as DHEA, while in women, it is 60.5 \pm 8.2%. The opposite conversion of DHEA to DHEAS is much smaller, 5.2% \pm 0.7% in men, and 6.25% \pm 0.54% in women.

Mean metabolic clearance rates (MCRs) were calculated using the constant infusion technique: The DHEA MCR is 2050 ± 160 L/day in men and 2040 ± 160 L/day in women, whereas the MCR for DHEAS is 13.8 ± 2.7 L/day in men and 12.5 ± 1.0 L/day in women. The differences in the clearance rates of DHEA and DHEAS are partly explained by different binding efficiencies with albumin. Circulating DHEA is primarily bound to albumin, with only minimal binding to sex hormone-binding globulin (SHBG); the remaining small amount is free. There is no known specific DHEA-binding protein. In comparison, DHEAS is strongly bound to albumin but not to SHBG, and an even smaller amount is protein free. Obesity results in increased MCR for DHEA from 2000 to 4000 L/day in women. A rise in MCR is also caused by insulin infusion in men (16).

Supplementation

Considerations related to the metabolism of DHEA become more complicated when it is administered as a dietary supplement (in the United States) or as a drug (in some other countries). The steroid is usually given orally in a single morning dose, as its constant interconversion to DHEAS and the long half-life of DHEAS make multiple dosing unnecessary. In addition, morning dosing mimics the natural rhythm of DHEA secretion. Doses ranging from 25 to 1600 mg/day have been used in different studies.

After an oral dose, the half-lives of DHEA/DHEAS are longer (24 hours) than those reported in intravenous tracer studies, which may reflect the conversion of DHEAS to DHEA (17). Oral administration of 20 to 50 mg of DHEA in patients with primary or secondary adrenal insufficiency restores serum DHEA and DHEAS concentrations to the range observed in normal young individuals, while a dose of 100 to 200 mg/day results in supraphysiological concentrations.

Different metabolic pathways for exogenous DHEA in relation to gender and age have been reported. DHEA levels after oral administration of 25 or 50 mg DHEA for eight days were persistently higher in women versus men (17). Similarly, oral administration of 200 mg of micronized DHEA in single or multiple doses for 15 days in healthy adult men and women resulted in higher serum concentrations and bioavailability (measured by DHEA C_{\max} and AUC) in women. The net increase in DHEAS levels was 21-fold in women and 5-fold in men (18). The metabolic fate of exogenous DHEA also differs by gender and age. While in pre- and postmenopausal women, DHEA is mostly transformed into androgens, in men it is preferentially metabolized into estrogens. Higher serum concentrations of DHEA, testosterone, and estradiol are achieved in elderly subjects (19).

THERAPEUTIC APPLICATIONS

DHEA Replacement in Adrenal Insufficiency

Patients with primary (Addison disease) and secondary adrenal insufficiency, typically exhibit very low, often undetectable, serum concentrations of DHEA(S) compared with values in age-matched control subjects. Despite optimal glucocorticoid and mineralocorticoid replacement, however, these patients often experience chronic fatigue, reduced sense of well-being, and lack of sexual interest.

Some studies have suggested that DHEA replacement exerts a positive effect on mood, vitality, sexuality, and overall well-being mostly in women and, to a lesser extent, in men, with chronic adrenal insufficiency (20–23). For example, oral administration of 50 mg/day of DHEA for four months to 24 women with adrenal insufficiency increased serum levels of DHEAS, androstenedione, testosterone, and androstenediol glucuronide, and improved overall well-being, mood, and sexual activity (20). In another study of 15 men and 24 women with Addison disease, administration of 50 mg/day of DHEA for three months corrected the hormonal deficiency and improved self-esteem, while it tended to enhance overall well-being, mood, and energy (21). However, other studies have failed to show similar effects (24–26). Moreover, a meta-analysis of 10 randomized placebo-controlled studies concluded that DHEA may improve health-related quality of life and depression in women with adrenal insufficiency, though the effect size (0.21; 95% confidence interval, 0.08–0.33; inconsistency (I^2) = 32%) was too small to support the routine use of DHEA in this patient group (27).

In the earlier studies, a single oral dose of DHEA (25–50 mg) was sufficient to keep serum concentrations of DHEA within the normal range, while signs of over-replacement included acne, hirsutism, or alopecia. Moreover, concerns have been raised about the effects of DHEA supplementation on the lipid profile and specifically on high-density lipoproteins (HDL) levels in hypoadrenal women (28), though it has been reported to improve their insulin resistance (29).

Because a pharmaceutically controlled DHEA preparation, as well as proof of effectiveness and safety in long-term phase III trials, are still lacking, replacement of DHEA in patients with adrenal insufficiency should be

restricted to those individuals whose well-being or libido is severely impaired despite adequate glucocorticoid and mineralocorticoid replacement.

DHEA Replacement in Adrenopause and Age-Related Disorders

As noted, aging is accompanied by profound decreases in circulating concentrations of DHEA and DHEAS in both sexes (5,7). Epidemiological studies suggest an association between the DHEA and DHEAS declines and the adverse effects of aging, albeit with gender differences.

One large, prospective observational study reported a small, but significant, inverse correlation between serum DHEAS concentrations and risk of cardiovascular mortality in men at 19-year follow-up, whereas in women, high DHEAS levels were associated with an increased risk of cardiovascular death at 12-year follow-up, and this trend lost significance at 19-year follow-up (30). Similar results were reported in another study of 963 men and 1171 women aged >65 years: all-cause and cardiovascular mortality were highest in men with DHEAS levels in the lowest quartile, whereas no significant association between circulating DHEAS and mortality was found in women (31). Other studies failed to demonstrate this inverse relationship in men (32). Positive correlations between low circulating DHEAS concentrations and depressed mood and bone loss have been reported in aged women (33). In comparison, DHEAS levels are reduced in men, with noninsulin-dependent diabetes mellitus (NIDDM) (34). Reports of an association between low DHEA levels and Alzheimer disease are conflicting.

It remains uncertain as to whether the DHEAS decline is simply a biomarker of aging, or is causally related to morbidity and mortality in the elderly. One study of the effects of oral administration of 50 mg/day of DHEA for six months to 13 men and 17 women aged 40 to 70 years showed restoration of DHEA and DHEAS levels to young-adult values, with improvement in physical and psychological sense of well-being, but not sexual interest, in both genders using a questionnaire for self-assessment. These effects were accompanied by increased serum levels of insulinlike growth factor 1 (IGF-I), reduced IGF-I binding protein-1 (IGFBP-1), and a significant decrease in apolipoprotein A1 and HDL-cholesterol in women, but no change in insulin sensitivity and body composition (35). Another study using 100 mg/day of DHEA for six months in 9 men and 10 women aged 50 to 65 years reported decreased fat mass and enhanced muscle strength in men, whereas increased levels of downstream androgens were detected in women (36). In a third study of 39 elderly men treated for three months with 100 mg/day of oral DHEA, no treatment effect on body composition or subjective well-being was found, whereas a significant reduction in HDL-cholesterol was reported (37).

In the largest study to date, 280 men and women aged 60 to 79 years were treated for 12 months with 50 mg/day of oral DHEA. No improvement in well-being was detected using a variety of validated tools. In addition, there were no significant changes in body composition, metabolic parameters, or muscle strength. However, a slight but significant increase in bone mineral density (BMD) at the femoral neck and the radius,

and an increase in serum testosterone, libido, and sexual function were observed in women >70 years old (38). Similar changes were reported in 14 women aged 60–70 years who were treated for 12 months with a 10% DHEA skin cream. In addition to a 10-fold increase in DHEA levels, the authors described increased BMD at the hip, and decreased osteoclastic and increased osteoblastic bone markers. Other changes included improved well-being, a reduced skinfold thickness, and lower blood glucose and insulin levels, with no adverse change in lipid profile (39). DHEA replacement did not affect BMD in other studies (36).

Little information is available regarding the effects of DHEA therapy on cardiovascular function and insulin sensitivity from interventional studies, other than that provided in the preceding text. The effects of DHEA treatment on lipid profile were evaluated in more than a dozen studies performed in men and women with various doses and routes of administration. The majority of these studies showed no effect of DHEA on plasma lipids (40).

In one study of 24 middle-aged men, administration of 25 mg/day of oral DHEA for 12 weeks decreased the plasma levels of plasminogen activator inhibitor type 1 (PAI-1), and increased dilatation of the brachial artery after transient occlusion (41).

In rodent models of NIDDM, dietary administration of DHEA consistently induced remission of hyperglycemia and increased insulin sensitivity. Some clinical studies in aged men and women have shown improved insulin sensitivity after DHEA replacement (39,42), whereas others have not confirmed those findings in women (35,43).

The effects of DHEA supplementation on cognitive function in healthy elderly people were recently reviewed in depth by Grimley et al. All randomized placebo-controlled trials enrolling people aged >50 without dementia to whom DHEA had been administered for more than one day were considered for inclusion. Five studies provided results from adequate parallel-group data. The authors concluded that findings from these controlled studies did not support any beneficial effect of DHEA supplementation on cognitive function in nondemented elderly people (44). Moreover, DHEA replacement did not affect memory in any of the controlled studies in healthy elderly, as previously discussed. Therefore, the use of DHEA supplementation to improve cognitive function should not be recommended in the elderly population at this time.

Potential Beneficial Effects of DHEA Supplementation

DHEA administration, often in large doses, has been proposed in the management of numerous disorders, including obesity, cancer, autoimmune diseases, AIDS, mood disorders, as well as in enhancing physical performance. The scientific evidence supporting the benefits of DHEA therapy in these conditions is, however, very limited.

Pharmacologic treatment with DHEA in mice genetically predisposed to become obese reduced weight gain and fat cell size. In obese rats, the steroid decreased food intake by 50%. In humans, some observational studies indicate a relationship between circulating DHEA and

DHEAS levels, body mass index (BMI) and weight loss, whereas others do not confirm this (45). Similar inconsistencies are encountered in interventional studies. Administration of a high oral dose of DHEA (1600 mg/day) decreased body fat and increased muscle mass, with no net change in body weight, in a small group of healthy young men. As mentioned earlier, a reduction in fat mass was also reported in healthy elderly men after six months administration of 100 mg/day of DHEA (36), whereas topical application of a 10% DHEA cream for one year decreased femoral fat and skinfold thickness in postmenopausal women (39). Other studies in healthy elderly individuals and in obese men failed to demonstrate changes in body fat after DHEA treatment (37,43).

DHEA has been reported to exhibit chemopreventive activity in mouse and rat models, although it has also been found to be hepatocarcinogenic in rats. Epidemiological research has revealed increased DHEA levels to be associated with a rise in risk of ovarian cancer and breast cancer in postmenopausal women, whereas decreased levels are linked with increased risk of bladder, gastric, and breast cancer in premenopausal women. To date, we are unaware of clinical studies documenting the effects of DHEA intervention on cancer initiation or propagation. Fluorinated DHEA analogs that cannot be converted into androgens or estrogens appear to have antiproliferative effects and have been tested in several pre-clinical cancers including bowel polyposis (46) and used without side effects in doses up to 200 mg/day orally for four weeks (47).

Increased antibody production in response to bacterial infections and decreased mortality from endotoxic shock were reported in DHEA-treated mice. In a study of 71 aged individuals, however, DHEA administration did not enhance antibody response to influenza vaccine (48). In contrast, 50 mg/day of oral DHEA increased the activity of natural killer cells by twofold, with a concomitant decrease in T-helper cells in postmenopausal women (49). In 28 women with mild-to-moderate systemic lupus erythematosus (SLE), oral treatment with 200 mg/day of DHEA for three to six months improved well-being and decreased disease activity and prednisone dosage requirements. The same DHEA dose administered orally for 56 days to patients with Crohn disease or ulcerative colitis decreased disease activity in a small, uncontrolled study (50). DHEA did not separate itself from placebo in a randomized controlled trial in patients with Sjögren syndrome (51). The effect of DHEA supplementation in SLE was recently reviewed more systematically. Analysis of the results from seven randomized placebo-controlled trials of at least three months duration revealed a modest but clinically significant beneficial effect of DHEA on measures of quality of life in SLE patients, whereas effects on measures of disease activity were inconsistent (52).

Serum DHEA and DHEAS levels in patients infected with HIV are directly related to CD4 cell counts and disease stage and progression. This observation has stimulated self-administration of DHEA as an adjunct to antiviral treatment by AIDS patients. In the only published placebo-controlled trial of DHEA in patients with advanced HIV disease, treatment with 50 mg/day orally

for four months resulted in increased DHEAS levels and improved mental function, with no change in CD4 cell count (53). These results were consistent with those from a previous open label study in 32 HIV-positive patients treated with DHEA doses of 200 to 500 mg/day for eight weeks (54).

Studies in adults and adolescents with major depressive disorders have revealed a blunted DHEA circadian variation, with low DHEA and high cortisol/DHEA ratio at 8:00 AM. In 22 patients with medication-free or stable major depression, supplementation with 30 to 90 mg/day of oral DHEA for six weeks decreased Hamilton depression scale scores as much as 50% (55). Similar results were reported in a well-controlled study in 15 patients aged 45 to 63 years with midlife-onset dysthymia who, after a three-week administration of 90 mg of DHEA, reported improvements in depressive symptoms (56). In a recent double-masked trial in schizophrenic patients with predominant negative symptoms, supplementation with 100 mg/day of DHEA also led to improvement in depression and anxiety (57). DHEA administration improves memory test results and decreases serum levels of β -amyloid in aging mice. In contrast, treatment with 100 mg of oral DHEA did not improve cognitive performance in patients with Alzheimer disease, similar to the findings reported in healthy elderly subjects (58).

DHEA is a popular dietary supplement among athletes. Nevertheless, at 150 mg/day orally, it did not improve body mass or strength in young male athletes and weight lifters (59,60). In contrast, increased quadriceps and lumbar strength were reported in healthy elderly men on DHEA replacement (36), and an increase in lean body mass of 4.5 kg was observed in healthy young men taking 1600 mg/day of DHEA for four weeks (61).

A summary of the various potential therapeutic applications of DHEA replacement/supplementation is presented in Table 2.

Table 2 Clinical Conditions for Which DHEA Use Has Been Proposed

Condition	Effect	References
Adrenal insufficiency	Improved general well-being, mood, sexual function	20-23
	No significant effects	24-27
Aging	Improved physical well-being, bone mineral density or sexual function	35,38,39
	Decrease in HDL or no effects	36,37
Autoimmune disease	Improved well-being, fatigue, disease activity in SLE patients, enhanced immune response	52
	No effect in HIV patients	53,54
Body composition	Decreased fat and increased muscle mass	36,61
	No changes	37,43
Insulin resistance	Improved insulin sensitivity	39
	No change	35
Depression	Improved mood	55-57
Alzheimer disease	No effect on cognitive function	58
Cardiovascular	Improved endothelial function	38
	No effect on lipids	40

CLINICAL PHARMACOLOGY AND TOXICOLOGY

Dietary/Nondietary Sources and Available Preparations

There are no known dietary sources of DHEA, although it was suggested that the supplement chromium picolinate could stimulate endogenous DHEA secretion. The Mexican plant "wild yam" contains some natural DHEA precursors, which cannot be converted into DHEA. However, sterol extracts of "wild yam" (such as diosgenin and dioscorea) are used to produce various forms of synthetic DHEA, including tablets, capsules, injectable esters (Gynodian Depot, Schering), sublingual and vaginal preparations, topical creams, lozenges, and herbal teas. DHEA is usually sold in tablets of 5 to 50 mg. A pharmaceutical-grade preparation (Prestara) has been developed for potential use as a prescription drug. During the manufacture of DHEA, other steroid-like compounds, like androstenedione, may be produced and could contaminate DHEA. Moreover, the real steroid content of the DHEA preparation sold over the counter may vary from 0% to 150% of the amount claimed (62). In addition, there is a lack of information about comparability or bioequivalence among the many products on the market or information about lot-to-lot variability of any particular product in terms of characterization (content) and standardization (contaminants).

Dosage and Administration

There is no consensus on a recommended dietary allowance (RDA) or optimal treatment dose for DHEA. Replacement with oral doses of 20 to 50 mg/day for men and 10 to 30 mg/day for women appears adequate to achieve DHEA/DHEAS levels similar to those in young adults, as suggested by most studies in subjects with adrenal or age-related DHEA/DHEAS deficiency, though oral doses as low as 5 mg/day have been reported to be effective. Higher DHEA doses may be necessary for patients with very low endogenous DHEA levels secondary to glucocorticoid administration or chronic disease. Doses of 200 to 500 mg and 200 mg/day have been used in patients with HIV and SLE, respectively. Serum DHEAS levels and its androgenic and estrogenic metabolites must be closely monitored during replacement to enable appropriate dose adjustments. Rigorous dose ranging studies are needed to determine the optimal doses to achieve a beneficial effect.

Adverse Reactions, Long-Term Effects, and Contraindications

DHEA appears to elicit few short-term side effects when used in the recommended doses. Women may experience mild hirsutism, increased facial sebum production, and acneiform dermatitis. Circulating concentrations of downstream androgens rise above young-adult values in healthy elderly women treated with 100 mg/day DHEA; however, the long-term consequences of this increase are unknown. No significant changes in complete blood count, urinalysis, hepatic, and thyroid indices were found in women after 28 days of treatment with 1600 mg DHEA/day (43). A dose escalation study of 750 to 2250 mg

oral DHEA conducted in 31 HIV-positive men revealed no serious dose-limiting toxicity (63).

Because of its potent androgenic and estrogenic effects, it would appear prudent to avoid DHEA replacement/supplementation in individuals with a personal or family history of breast, ovarian, or prostate cancer. This would seem especially important for postmenopausal women, considering the demonstrated direct correlation between circulating concentrations of DHEA and breast and ovarian cancers in this group (46), and the reported increase with DHEA supplementation in free IGF-1 (64). Caution may also be appropriate in HIV patients, since high DHEA levels have been implicated in the pathogenesis of Kaposi's sarcoma. Moreover, increased insulin resistance and decreased cholesterol and HDL after administration of a high dose 1600 mg/day of DHEA for four weeks have been reported in aged women (43).

DHEA administration is not recommended for people younger than 40 years of age, unless there is a documented deficiency state. It should be avoided during pregnancy, lactation, and in persons younger than 18 years, as dosage and safety of the treatment under these conditions have not been evaluated.

Known Drug Interactions

Drugs known to interfere with DHEA and/or DHEAS include various hormone preparations, drugs acting on the CNS, cardiovascular drugs, adrenergic and adrenergic blocking agents, and anti-infective agents. Synthetic glucocorticoids such as dexamethasone are the most potent suppressors of DHEA and DHEAS. DHEA and/or DHEAS levels are known to be decreased in patients taking aromatase inhibitors, oral contraceptives, dopaminergic receptor blockers, insulin, troglitazone, and multivitamins, or fish oil. They are also decreased due to the induction of the cytochrome P450 enzymes, by carbamazepin, phenytoin, or rifampicin. Metformin (a biguanide antihyperglycemic drug) and calcium channel blockers are shown to increase DHEA and DHEAS levels. The effect of alcohol is controversial (65).

Compendial/Regulatory Status

In the early 1980s, DHEA was widely advertised and sold in U.S. health food stores as an "anti-aging," "anti-obesity," and "anti-cancer" nonprescription drug. However, on the basis of unknown potential long-term risks, and following the ban by the International Olympic Committee, in 1985 the U.S. Food and Drug Administration reclassified DHEA as a prescription drug. In October 1994, the U.S. Dietary Supplement Health and Education Act allowed DHEA to be sold again as an over-the-counter dietary supplement, as long as no claims are made regarding therapeutic efficacy. DHEA remains available over the counter in the United States, as it was not reclassified as an anabolic steroid, and hence a controlled substance, in the 2004 Anabolic Steroid Control Act.

CONCLUSIONS

Despite a considerable amount of research related to DHEA, and its alleged utility to sustain "eternal youth," several key questions remain unanswered. For example, the physiologic function(s), regulation, and mechanisms of actions of DHEA remain unknown, and a causal link between age-related declines in DHEA and adverse effects of aging has not been proven. Results from clinical studies suggest that DHEA may be beneficial in some patients with adrenal insufficiency, whereas data from intervention studies in healthy older people have been inconclusive, save for some modest gender differences in selected outcome measures. Well-characterized and standardized products need to be evaluated for safety and efficacy, starting with dose ranging to determine an optimal dose. Because DHEA can be converted to estrogen and testosterone, its potential adverse effects in patients with breast or prostate cancer need to be determined. Long-term, well-designed clinical studies, with clear end points, will be necessary before the beneficial and/or detrimental effects of "replacement" or "pharmacological" DHEA therapies in human aging and disease can be firmly established.

Echinacea Species

Rudolf Bauer and Karin Woelkart

INTRODUCTION

Echinacea is a herbal medicine that has been used for centuries, customarily as a treatment for common cold, coughs, bronchitis, upper respiratory infections (URIs), and inflammatory conditions. It belongs to Heliantheae tribe of the Asteraceae (Compositae) family, and the nine species of these perennial North American wildflowers have a widespread distribution over prairies, plains, and wooded areas.

BACKGROUND

Three species of *Echinacea* are used medicinally: *E. purpurea* (Fig. 1), *E. pallida* (Fig. 2), and *E. angustifolia* (Fig. 3). In the United States of America, *Echinacea* preparations have been the best selling herbal products in health food stores. However, an analysis reveals that completely different preparations are sold under the name *Echinacea* using different plant parts and different extraction solvents (1). The most investigated preparation, which is mainly available on the German market, contains the expressed juice of *E. purpurea* aerial parts. Besides this, hydroalcoholic tinctures of *E. purpurea* aerial parts and roots, as well as from *E. pallida* and *E. angustifolia* roots, can be found (2,3). In North America, especially, it is also common to sell encapsulated powders from aerial parts and roots of these three species.

Preclinical studies indicate that *Echinacea* constituents modulate immune mechanisms and there is increasing evidence that *Echinacea* preparations containing alkamides can suppress stress-related cellular immune responses. As reviewed by Chicca et al. (4), the interaction of alkamides with the cannabinoid receptor type-2 (CB₂), which is a modulator of inflammation, may provide a mechanistic basis for the anti-inflammatory and immunomodulatory effects exerted by purple coneflower. *Echinacea* alkamides are now considered as a new class of cannabinomimetics (5,6). Recent findings suggest that *Echinacea* has a modulatory role on the innate immune system, able to both stimulate and inhibit the immune response. Since *Echinacea*-derived alkamides significantly suppressed T-lymphocytes (7), it is apparent that the multiplicity and diversity of parts of various plants, methods of extraction, and solvents used, as well as the components on which the extracts have been standardized, have hampered clear recommendations regarding *Echinacea* usage.

Several reviews on the evidence regarding the effectiveness of orally ingested *Echinacea* extracts in reduc-

ing the incidence, severity, or duration of acute URIs have been published. The majority of trials investigated whether *Echinacea* preparations shorten the duration or decrease the severity of symptoms of the common cold (for reviews see 5,8–12). A recent Cochrane review (10) concluded that especially preparations based on the aerial parts of *E. purpurea* might be effective for the early treatment of colds in adults, but results are not fully consistent. Beneficial effects of other *Echinacea* preparations for preventative purposes might exist, but have not been shown in independently replicated rigorously randomized trials. Therefore, further clinical studies are needed to evaluate the therapeutic role of *Echinacea* preparations. Many of the in vivo studies performed so far used phytochemically insufficiently characterized *Echinacea* preparations.

The regulatory status of *Echinacea* products is variable. In the United States, they are considered as dietary supplements, and manufacturers can therefore produce, sell, and market herbs without demonstrating safety and efficacy first, as is required for pharmaceutical drugs. In Canada, they are regulated as Natural Health Products (NHPs), and in several European countries they have drug status. The EMEA (European Medicines Agency) Committee on Herbal Medicinal Products (HMPCs) has published the following guidance documents for *Echinacea* products (www.emea.europa.eu):

- Community Herbal Monograph on *Echinacea purpurea* (L.) Moench, herba recens (13)
- Community Herbal Monograph on *Echinacea purpurea* (L.) Moench, radix (14)
- Community Herbal Monograph on *Echinacea pallida* (Nutt.) Nutt., radix (15)
- Community List Entry for *Echinacea purpurea* (L.) Moench, herba recens (16)

For HMPCs published as a Community Herbal Monograph, the industries in general have still more possibilities in change. In contrast, entries in the Community List are legally binding to applicants and competent authorities.

ACTIVE PRINCIPLES, PHARMACOLOGICAL EFFECTS, AND STANDARDIZATION

The constituents of *Echinacea*, as in any other plant, cover a wide range of polarity, ranging from the polar polysaccharides and glycoproteins, via the moderately polar caffeic acid derivatives, to the rather lipophilic polyacetylenes

Figure 1 *Echinacea purpurea*.

and alkamides. This makes it necessary to study separately the activity of different polar extracts of *Echinacea*, such as aqueous preparations, alcoholic tinctures, and hexane or chloroform extracts.

Polysaccharides and Glycoproteins

Systematic fractionation and subsequent pharmacological testing of the aqueous extracts of the aerial parts of *E. purpurea* led to the isolation of two polysaccharides (PS I and PS II) with immunostimulatory properties. They were shown to stimulate phagocytosis in vitro and in vivo, and enhance the production of oxygen radicals by macrophages in a dose-dependent way. Structural analysis showed PS I to be a 4-*O*-methylglucuronarabinoxylan with an average MW of 35,000

Figure 2 *Echinacea pallida*.

Figure 3 *Echinacea angustifolia*.

Da, while PS II was demonstrated to be an acidic arabinorhamnogalactan of MW 45,000 Da. A xyloglucan, MW 79,500 Da, was isolated from the leaves and stems of *E. purpurea* (17), and highly water-soluble fructans have been recently isolated from *E. purpurea* (L.) Moench roots (18). Polysaccharides from *E. angustifolia* have also been found to possess anti-inflammatory activity (19). In a Phase-I clinical trial, a polysaccharide fraction (EPO VIIa), isolated from *E. purpurea* tissue culture and injected at doses of 1 and 5 mg, caused an increase in the number of leukocytes, segmented granulocytes, and tumor necrosis factor- α (TNF- α) (20). Three glycoproteins, MW 17,000, 21,000, and 30,000 Da, have been isolated from *E. angustifolia* and *E. purpurea* roots. The dominant sugars were found to be arabinose (64–84%), galactose (1.9–5.3%), and glucosamines (6%). The protein moiety contained high amounts of aspartate, glycine, glutamate, and alanine (21). An enzyme-linked immunosorbent assay (ELISA) method has been developed for the detection and determination of these glycoproteins in *Echinacea* preparations (22). In 2005, an arabinogalactan protein (AGP) and an arabinan were isolated from the roots of *E. pallida* (Nutt.) Nutt (23). Most AGPs contain mostly carbohydrate moieties (>90%) along with a small amount of protein (<10%). Also information concerning the protein-polysaccharide linkage type has recently been published,

and hydroxyproline (42.9% w/w) was detected as the dominant amino acid and was identified as the major amino acid responsible for the binding between the protein and the AG subunits via an *O*-glycosidic linkage (24). Purified extracts containing these glycoprotein-polysaccharide complexes exhibited B-cell stimulating activity and induced the release of interleukin-1 (IL-1), TNF- α , and interferon- α,β (IFN- α,β) in macrophages, which could also be reproduced in vivo in mice (21).

In a study performed in 2002, the influence of an oral administration of a herbal product, consisting of an aqueous-ethanolic extract of the mixed herbal drugs *Thujae summities*, *Baptisia tinctoriae* radix, *E. purpurea* radix, and *E. pallidae* radix, standardized on *Echinacea* glycoproteins, on cytokine induction, and antibody response against sheep red blood cells was investigated by Bodinet et al. (25) in mice. This administration caused a significant enhancement of the antibody response against sheep red blood cells, inducing an increase in the numbers of splenic plaque forming cells and the titers of specific antibodies in the sera of the treated animals (25).

The influence of the same extract on the course of Influenza A virus infection in Balb/c mice was also tested. The data show that the oral treatment with this aqueous-ethanolic extract induced a statistically significant increase in the survival rate, prolonged the mean survival time, and reduced lung consolidation and virus titer (26). An *Echinacea* polysaccharide enriched fraction isolated from *E. purpurea* aerial parts was able to exert an antiviral action on the development of recurrent herpes simplex virus type-1 (HSV-1) disease when supplied prior to infection (27). Hwang et al. (28) showed that macrophages respond to purified polysaccharide and also alkamide preparations. Adherent and nonadherent mouse splenocyte populations were incubated in vitro with *E. purpurea* liquid extract (fresh *Echinacea* root juice, mature seed, fresh leaf, and fresh fruit juice extracted in 40–50% alcohol), or with water or absolute alcohol (25 mg dry powder/mL of solvent) soluble *E. purpurea* dried root and leaf extract preparations. The immune stimulatory ability of components contained within these *Echinacea* extracts offers insight into possible therapeutic potential to regulate nonadherent lymphocytes in immune responses and activation events. The use of flow cytometry demonstrates a link between the polysaccharides in *Echinacea* and the immunostimulatory effect that has therapeutic relevance. It was suggested that the main immunostimulatory activity of *Echinacea* resides in the water-soluble materials rather than the lipoidal small molecules (29).

Caffeic Acid Derivatives

Alcoholic tinctures of *Echinacea* aerial parts and roots are likely to contain caffeic acid derivatives (Figs. 4–6). Extracts of different species and plant parts of *Echinacea* can be distinguished by thin layer chromatography (TLC) or high-performance liquid chromatography (HPLC) analysis (2). Also, capillary electrophoresis [micellar electrokinetic chromatography (MEKC)] has been successfully applied for the analysis of caffeic acid derivatives in *Echinacea* extracts and enables the discrimination of the species (30). The roots of *E. angustifolia* and *E. pallida* have been shown to contain 0.3–1.7% echinacoside (1) (2). Both species can

Figure 4 Main phenylpropanoid glycosides found in *Echinacea* species.

be discriminated by the occurrence of 1,3- and 1,5-O-dicaffeoyl-quinic acids (3, 4), which are only present in the roots of *E. angustifolia*. Recently, it has been reported that cynarin, the 1,3-dicaffeoyl-quinic acid, blocked the interaction between the CD28 of T-cell receptor and CD80 of antigen presenting cells under the condition of 1:1 ratio of T-cell and B-cell in vitro. This *Echinacea* component is the first small molecule that is able to specifically block the CD28-dependent pathway of T-cell activation and has therefore great potential as an immunosuppressive agent (31). Echinacoside has anti-oxidant (32), low antibacterial, and antiviral activity, but does not show immunostimulatory effects (17). It is also reported that echinacoside inhibits hyaluronidase (33) and protects collagen type III from free radical-induced degradation in vitro (34). The aerial parts of *E. angustifolia* and *E. pallida* have been shown to contain verbascoside (2), a structural analog of echinacoside (1). The roots of *E. purpurea* do not contain echinacoside, but cichoric acid (2*R*,3*R*-dicaffeoyl-tartaric acid; 6) and caftaric acid (monocaffeoyl tartaric acid; 5). Cichoric acid (6) is also the major polar constituent in the aerial parts of *Echinacea* species. Echinacoside (1) and cichoric acid (6) have also been produced in tissue cultures of *E. purpurea* and *E. angustifolia* (17). The latter acid (6) has been shown to possess phagocytosis stimulatory activity in vitro and in vivo, while echinacoside (1), verbascoside (2), and 2-caffeoyl-tartaric acid (5) did not exhibit this activity (17). Robinson described cichoric acid as an inhibitor

Figure 5 Quinic acid derivatives from *Echinacea* species.

Figure 6 Tartaric acid derivatives from *Echinacea* species.

of human immunodeficiency virus type-1 (HIV-1) integrase (35). It is especially abundant in the flowers of all *Echinacea* species and the roots of *E. purpurea* (1.2–3.1% and 0.6–2.1%, respectively). Much less is present in the leaves and stems. *E. angustifolia* contains the lowest amount of cichoric acid (2). The content, however, strongly depends on the season and the stage of development of the plant and is highest at the beginning of the vegetation period and decreases during plant growth (36). Nüsslein et al. found that polyphenol oxidases (PPO) are responsible for the oxidative degradation of exogenous and endogenous caffeic acid derivatives (37,38). Apart from cichoric acid, echinacoside (1) and cynarin (3) from *E. angustifolia* roots are also highly susceptible to enzymatic degradation and oxidation in hydroalcoholic solutions during the extraction process. During the 16 days after extraction of *E. angustifolia* roots with 60% (v/v) ethanol/water and storage at 4°C, a decline to 0 was observed in the content of echinacoside (1) and cynarin (3) from 0.25 mg/mL extract and 0.09 mg/mL extract, respectively (39). In order to standardize *Echinacea* preparations and guarantee a consistent content of caffeic acid derivatives, it is vital to control this enzymatic activity.

Alkamides

Striking differences have been observed between the lipophilic constituents of *E. angustifolia* (alkamides; Fig. 7) and *E. pallida* roots (ketoalkenynes; Fig. 8). *E. purpurea* roots also contain alkamides, however, mainly with two double bonds in conjugation to the carbonyl group, while *E. angustifolia* primarily has compounds with a 2-monoene chromophore. The chief lipophilic constituents of *E. pallida* roots have been identified as ketoalkenes and ketoalkynes with a carbonyl group in the 2-position (2). The main components are tetradeca-8Z-ene-11,13-diyn-2-one (17), pentadeca-8Z-ene-11,13-diyn-2-one (18), pentadeca-8Z,13Z-diene-11-yn-2-one (19), pentadeca-8Z,11Z,13E-triene-2-one (20), pentadeca-8Z,11E,13Z-triene-2-one (21), and pentadeca-8Z,11Z-diene-2-one (22). They occur only in trace amounts in *E. angustifolia* and *E. purpurea* roots. Therefore, they are suitable as markers for the identification of *E. pallida* roots. However, it has been observed

Figure 7 Main alkamides found in *Echinacea* aerial parts and *E. purpurea* and *E. angustifolia* roots.

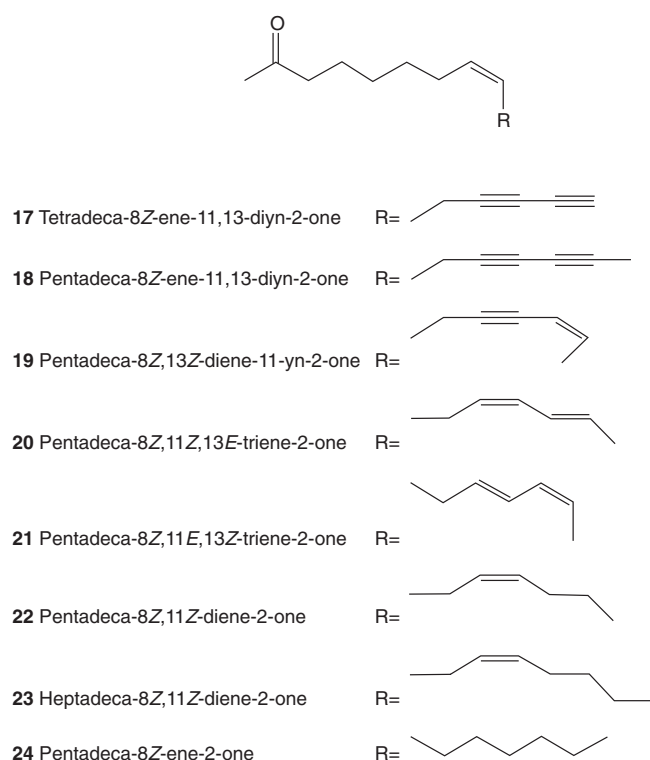

Figure 8 Ketoalkenes and ketoalkynes found in *E. pallida* roots.

that these compounds undergo auto-oxidation when the roots are stored in powdered form. Then, the hydroxylated artifacts, 8-hydroxy-9E-ene-11,13-diyn-2-one (25), 8-hydroxy-pentadeca-9E-ene-11,13-diyn-2-one (26), and 8-hydroxypentadeca-9E,13Z-diene-11-yn-2-one (27), can be primarily found (Fig. 9), often with only small residual quantities of the native compounds. Hence, the roots of *E. pallida* are best stored in whole form.

Approximately 15 alkamides have been identified as important lipophilic constituents of *E. angustifolia* roots. They are mainly derived from undeca- and dodecanoic acid, and differ in the degree of unsaturation and the configuration of the double bonds (Fig. 7). The main structural type is a 2-monoene-8,10-diynoic acid isobutylamide, and some 2'-methyl-butylamides have also been found. In

Figure 9 8-Hydroxy-ketoalkenyne formed via auto-oxidation in powdered *E. pallida* roots.

E. purpurea roots, 11 alkamides have been identified with the isomeric mixture of dodeca-2E,4E,8Z,10E/Z-tetraenoic acid isobutylamides (11, 12) as the major compounds (17).

The aerial parts of all three *Echinacea* species contain alkamides of the type found in *E. purpurea* roots, and also with dodeca-2E,4E,8Z,10E/Z-tetraenoic acid isobutylamides (11, 12) as the main constituents (2). A series of pharmacological experiments have shown that *Echinacea* extracts containing alkamides have significant anti-inflammatory and immunomodulatory properties. Among the many pharmacological effects reported, modulation of macrophages and polymorphonucleocytes (PMN) immune cells and effects on cytokine/chemokine expression in human cells have been demonstrated most convincingly. Furthermore, inhibition of cyclooxygenase is known as an effective strategy to suppress pain and inflammation. Alkamides isolated from the roots of *E. angustifolia* inhibited cyclooxygenase-2 (COX-2)-dependent prostaglandin E₂ formation, but did not inhibit COX-2 expression at the transcriptional or translational level (5,8,9,40–42).

Determination of the alkamide content (dodeca-2E,4E,8Z,10E/Z-tetraenoic acid isobutylamides) in the different plant parts showed that it accumulates primarily in the roots and inflorescences, the highest being found in *E. angustifolia*. *E. pallida* roots contain only trace amounts, roots of *E. purpurea* 0.004% to 0.039%, and those of *E. angustifolia* 0.009% to 0.151%. The yield in the leaves is 0.001% to 0.03% (17). In a recent study, 62 commercial dried root and aerial samples of *E. purpurea* grown in eastern Australia were analyzed for the medicinally active constituents. Total concentration in root samples was 6.2 ± 2.4 mg/g, and in aerial samples was 1.0 ± 0.7 mg/g (43).

In 2001, Dietz et al. (44) reported the presence of dodeca-2E,4E,8Z,10E/Z-tetraenoic acid isobutylamides (11, 12) in human blood after oral administration of an ethanolic extract of *E. purpurea*. More recently, a study showed that the absorption maximum (C_{\max}) of dodeca-2E,4E,8Z,10E/Z-tetraenoic acid isobutylamides (11, 12) is reached 30 minutes after oral application. Due to these results, the mucous membrane of the mouth is most likely the major area of absorption (45). Jager et al. investigated the permeability of isobutylamides (11, 12) through Caco-2 monolayers. They found that the alkamides were almost completely transported from the apical to the basolateral side of the monolayer in six hours by passive diffusion and that no significant metabolism occurred (46). Matthias et al. (47) investigated the bioavailability of caffeic acid derivatives and alkamides also using Caco-2 monolayers. The caffeic acid conjugates (caftaric acid, echinacoside, and cichoric acid) permeated poorly through the Caco-2 monolayers although one potential metabolite, cinnamic acid, diffused readily with an apparent permeability (P_{app}) of 1×10^{-4} cm/sec, while alkamides were found to diffuse with P_{app} ranging from 3×10^{-6} to 3×10^{-4} cm/sec. Close monitoring of the transport for six hours revealed a nearly complete transfer to the basolateral side without significant metabolism. Transport experiments performed at 4°C showed only a slight decrease, which is a strong hint that dodeca-2E,4E,8Z,10E/Z-tetraenoic acid isobutylamides (11, 12) cross biological membranes by passive diffusion. These data suggest that alkamides are more likely than caffeic acid conjugates to

pass through the intestinal barrier and thus be available for influencing an immune response (47).

Based on these in vitro studies and the performance of eight pharmacokinetic studies since 2005, evidence is given that alkamides are bioavailable in relevant concentrations after oral administration of *Echinacea* preparations or pure compounds (5). In all pharmacokinetic studies performed so far, the time to reach the mean concentration maximum after administration of liquid *Echinacea* preparations (*E. angustifolia* or *E. purpurea*) was approximately 30 minutes. T_{\max} after administration of *Echinacea* tablets, which has been investigated in two clinical studies, was varying within 45 minutes to 2.3 hours (5). As it has also been shown for *Echinacea* tinctures that more concentrated preparations needed longer to attain T_{\max} . Besides bioavailability, information concerning the distribution in tissues is an important issue in the evaluation of the systemic exposure and a prerequisite for the interpretation of in vitro pharmacological testing. The pharmacokinetic and tissue distribution of the dodeca-2E,4E,8Z,10E/Z-tetraenoic acid isobutylamides (tetraenes), the main alkamides in *Echinacea* preparations, has been recently investigated and demonstrated a rapid absorption and distribution to the examined tissues (liver and four different brain regions) with a passage across the blood-brain barrier (BBB). The highest concentration was found in the striatum. The total amount of tetraenes in plasma was calculated as area under the curve ($AUC_{0-\infty}$) (794 min · ng/mL) and approximately 13%~45% of that found in different brain parts (1764–6192 min · ng/mL), and 63% of that in liver tissues (1254 min · ng/g). The C_{\max} in plasma was 26.4 ng/mL, while the C_{\max} in the different brain regions varied between 33.8 ng/g and 46.0 ng/g. The appearance in brain tissues offers new pharmacological options of alkamides containing *Echinacea* preparations with the emphasis on cannabinoid receptor interaction between the immune system and the central nervous system (48). Since alkamides show structural similarity with anandamide, an endogenous ligand of cannabinoid receptors, it was found that alkamides bind significantly to CB₂ receptors, which is now considered as a possible molecular mode of action of *Echinacea* alkamides as immunomodulatory agents (5,49). At the same time, Gertsch et al. demonstrated the modulation of TNF- α gene expression and multiple signal transduction pathways by *Echinacea* alkamides and postulated a mechanism related to cannabinoid receptors. To ascertain whether CB₂ was the receptor subtype involved in the observed effects, a CB₂ antagonist was used in combination with the dodeca-2E,4E,8Z,10E/Z-tetraenoic acid isobutylamides. The specific antagonist strongly abolished TNF- α transcription and thus indicated a strict peripheral cannabinoid-mediated process (40,41). Effects on CB₂ receptor-containing immune cells in humans were evaluated in a randomized, single dose, crossover ex vivo study with lipopolysaccharide (LPS)-stimulated blood cells after in vivo administration of two *E. purpurea* preparations standardized on 0.07 mg dodeca-2E,4E,8Z,10E/Z-tetraenoic acid isobutylamides (EchinaforceTM tincture and tablets). Both forms of medication led to a significant decrease in production of proinflammatory cytokines (IL-8 and TNF- α), while changes in IL-6 concentration were not statistically significant (5). IL-8 and TNF-

α are proinflammatory cytokines. Therefore, the effect of the *Echinacea* preparations can be considered as an anti-inflammatory action and corresponds with the observed in vitro effects of alkamides. Also the direct effects of alkamides on T-lymphocytes, which are key mediators of antiviral immunity, have been investigated by testing inhibition of IL-2 production (50). This can explain why the symptoms of a common cold, like sore throat, can be reduced. In summary, a lot of recent pharmacological data suggest that *Echinacea* alkamides may not only have immunostimulatory but also anti-inflammatory and antiviral activity by a reduction in NO, TNF- α , IL-8, IL-2, and COX-dependent prostaglandin E₂ formation in different cell types and assays used.

From the above, it is obvious that not a single, but several constituents, like the alkamides, cichoric acid, glycoproteins, and polysaccharides, are responsible for the immunostimulatory activity of *Echinacea* extracts, and the application of extracts appears to be reasonable. However, conformity of these extracts is a must for generating consistent products and reproducible activity.

CLINICAL EFFICACY

Several dozen human experiments—including a number of blind randomized trials—have reported health benefits of *Echinacea* preparations. So far, clinical efficacy has been studied in randomized controlled clinical trials for cold pressed juice and hydroalcoholic tincture/extract of *E. purpurea* aerial parts, a standardized extract from *E. purpurea* roots (hydroalcoholic tincture/extract), a hydroalcoholic extract of *E. pallida* roots, and for *E. angustifolia* root tinctures. All of them have used a variety of different *Echinacea* preparations and study designs. Most importantly, the phytochemical profile of the preparations was not determined or not reported in most of the studies. Since different *Echinacea* preparations have varying phytochemical profiles due to the use of diverse species, plant parts, and extraction procedures, the variation in reported clinical effectiveness may be due to discrepancies in the chemical profile. In 16 randomized controlled trials summarized in the latest Cochrane database, only eight (50%) reported the exact characterization of the herbal remedy being used (10). In three experimental infection studies pooled by Schoop et al. (51), only one (33%) has been included without content details of the tested *Echinacea* product. In the 14 randomized clinical trials included in the meta-analysis by Shah et al. (11), five (36%) reported the chemical profiling of the herbal product used. Therefore, the newly published meta-analysis pooled results for all *Echinacea* preparations, although the original publication did not adequately describe the preparations tested. This lack of information needs to be taken into account when research on *Echinacea* is evaluated.

The most robust data come from trials testing *E. purpurea* extracts in the treatment for acute URI. A recent Cochrane review (10) summarized 16 randomized clinical trials of *Echinacea* to assess whether there is evidence that *Echinacea* preparations are (i) more effective than no treatment, (ii) more effective than placebo, (iii) similarly effective to other treatments in the prevention and treatment of the common cold. The authors concluded that there is

some evidence that preparations based on the aerial parts of *E. purpurea* might be effective for the early treatment of colds in adults.

Besides the Cochrane database review, two further meta-analyses have been published. In one meta-analysis, all performed clinical trials were pooled regardless of the product tested or the trial approach used (11), the second included only trials with experimentally induced infections (51). The meta-analysis by Shah et al. included two sets of studies: nine studies investigating whether *Echinacea* compounds prevent colds and seven studies investigating whether they shorten their duration. It has been stated that there is a significant improvement of common cold after taking *Echinacea*. In detail, *Echinacea* decreased the odds of developing the common cold by 58% and the duration of a cold by 1.4 days (11). The other meta-analysis of three preventative trials using an experimental virus challenge model showed that the odds of experiencing a clinical cold were 55% higher with placebo than with *Echinacea* (51). In this meta-analysis a study, published in the *New England Journal of Medicine*, evaluating the effect of chemically defined extracts from *E. angustifolia* roots on rhinovirus type 39 infection was included. Without pooling, the extracts did not have clinically significant effects on infection with a rhinovirus or on the clinical illness (52). These results and information should be a motivation to conduct larger prevention trials in the future.

As with most medications for the treatment of the common cold, the clinical data on *Echinacea* so far are not conclusive. There is a clear indication that preparations from the aerial parts and roots of *E. purpurea* may be effective. Preparations from *E. angustifolia* and *E. pallida* roots need further controlled clinical trials, in order to provide a better evidence for clinical efficacy (12).

CLINICAL PARTICULARS

Dosage Information

For internal use, the daily dose for aerial parts of *E. purpurea* for adults is 6 to 9 mL of pressed juice or equivalent preparations, 3 × 60 drops of a tincture (1:5, ethanol 55% v/v) or dried expressed juice equivalent to 8 to 18 g of the herbal substance, divided in two to four doses (13). For dried roots, the recommended daily dose is 3 × 300 mg one chewable tablet containing 40 mg extract (6.5:1) of *E. purpurea* roots and corresponding to 260 mg of herbal substance, every second hour (maximum nine tablets a day) (14). For external use, semisolid preparations with a minimum of 15% of pressed juice are recommended (16). For *E. pallida* roots, the recommended daily dosage of Commission E is tincture 1:5 with 50% (v/v) ethanol from native dry extract (50% ethanol, 7–11:1), corresponding to 900 mg herb (53), three times daily one tablet containing 30 mg dry extract (4–8:1) of *E. pallida* roots, four times daily two tablets containing 12 mg dry extract (4–8:1), or five times daily 25 drops containing 100% tincture (1:5) (15). The use in children younger than 1 year is contraindicated, and the use in children between 1 and 12 years of age is not recommended. The therapy should start at first signs of common cold. If the symptoms persist longer than 10 days during the use of the medicinal product, a doctor or a qualified health care practitioner should be consulted.

Adverse Effects and Herb–Drug Interactions

The safety profile of *Echinacea* has been based on the very few reported serious adverse events and reports from several clinical trials that showed a low frequency of side effects. Parnham (54) reported 13 adverse events that were possibly associated with *Echinacea* use in Germany between 1989 and 1995, and 4 were determined to be causal. All the adverse events were reported as allergic reactions. Taylor et al. (55) found an increased risk of rash when children of 2 to 11 years received *Echinacea* compared with those who received placebo. Mullins and Heddle (56) reported 51 possible cases of *Echinacea*-related allergy, of which 26 were suggestive of possible immunoglobulin E-mediated hypersensitivity. Allergic cross-reaction with daisy family members has been reported.

Some possible side effects from the German health authorities list (53):

- In rare cases, hypersensitivity reactions might occur. For drugs with preparations of *Echinacea*, rash, itching, rarely face swelling, shortness of breath, dizziness, and blood pressure drop have been reported.
- In case of diabetes, the metabolic status may worsen (53).

Perri et al. (57) reviewed the evidence for the use of *Echinacea* during pregnancy and lactation via seven electronic databases. They found good scientific evidence from a prospective cohort study that oral consumption of *Echinacea* during the first trimester does not increase the risk for major malformations. They reported that *Echinacea* is nonteratogenic when used during pregnancy. Caution should be maintained while using *Echinacea* during lactation until further high-quality human studies can determine its safety. In contrast, in 2007, there was the first study conducted to evaluate whether pharmaceuticals containing alcoholic extracts of *E. purpurea* given to pregnant mice influence angiogenic activity and may then lead to severe developmental disturbances. They found an increase in angiogenic activity of tissue homogenates in Esberitox group and a diminution in case of Immunol forte. The growth factor concentration was lower in all groups compared to the control. They concluded that there is some possibility that pharmaceuticals containing *E. purpurea* might influence fetal development in human also, because they may interfere with embryonal angiogenesis, and should not be recommended for pregnant women (58).

The German Commission E monograph cautions the use of *Echinacea* in persons who have autoimmune diseases, progressive systemic diseases, such as tuberculosis, multiple sclerosis, leukoses, collagenoses, and HIV infection. The warnings are based not on solid clinical evidence but on the theoretical possibility that the immune-mediated inflammatory mechanism of these diseases can be exacerbated by the immunostimulating properties of *Echinacea*.

No significant herb–drug interactions with *Echinacea* have been reported. Four studies were clinical trials and nine were in vitro assays, but most of the studies did not contain complete information about the concentration of extract used (59). No phytochemical analysis of the extracts was reported and limit the inferences that can be

drawn from these studies. A common problem of many herb–drug interaction reports is that investigators fail to report species, plant part used, preparation type, and concentrations assayed, and/or dose, each of which may affect the accuracy of reporting and the potential for herb–drug interactions.

Currently, there are no rational reports available on herb–drug interactions of any *Echinacea* product. Both *E. purpurea* aerial parts and roots appear to have a relatively low potential to generate cytochrome P450 (CYP 450) herb–drug interactions in vivo involving CYP1A2 and CYP3A4 (60). There is little if any effect of *E. purpurea* on systemic *p*-glycoprotein-mediated transport mechanism in vivo (61,62).

It can be concluded that there is a very low incidence of side effects associated with *E. purpurea*, since, in comparison with the large proportion of the population using *Echinacea* yearly (>10 million), there have been no known reported major outbreaks of side effects or death. Also in long-term treatment, the expressed juice of *E. purpurea* was shown to be well tolerated (54).

CONCLUSIONS

Echinacea, one of the most popular botanical supplements in North America, is employed as an immunomodulator, with antimicrobial and anti-inflammatory properties. So far, the overall therapeutic activity of *Echinacea* cannot be attributed to any single constituent. Pharmacological effects related to immune functions have been demonstrated for both high- and low-molecular-weight constituents. Compounds from the classes of caffeic acid derivatives, alkamides, polysaccharides, and glycoproteins are regarded as the most relevant constituents. Recent experiments have demonstrated that alkamides are detectable in human blood in relevant concentrations after oral administration of *Echinacea* preparations. Moreover, it has been shown that the main alkamides cross the BBB and bind to CB receptors, which is now considered as a possible molecular mode of action of *Echinacea* alkamides as immunomodulatory agents. Employing various species, plant parts, and extraction procedures results in different *Echinacea* preparations having distinguished phytochemical profiles. Clinical effectiveness may vary because of discrepancies in the chemical profile. Standardization of botanicals should guarantee that preparations contain therapeutically effective doses of active principles and should assure consistent batch-to-batch composition and stability of the active constituents. Also, clinical trials should be performed only with well-characterized *Echinacea* preparations.

Elderberry

Madeleine Mumcuoglu, Daniel Safirman, and Mina Ferne

INTRODUCTION

Sambucus nigra Linnaeus is a small deciduous tree, which grows widely in Europe, Western and Central Asia, and North Africa. It is often planted as a decorative tree in gardens and public parks. The English name Elder comes from the Anglo-Saxon word "aeld," which means fire. The hollow stems of the young branches were used for building a fire (1). The generic name *Sambucus* comes from the Greek word "Sambuca," an ancient musical instrument, made from the wood of this tree (1).

All parts of the tree have long been used in traditional medicine, that is, the bark, the fresh and dried leaves, the dried flowers, the fresh and dried fruits, and the dried roots. The tree is propagated by seeds sown in autumn, as well as by greenwood cuttings in early summer and by hardwood cuttings in winter. The flowers contain flavonoids, cyanogenic glycosides, triterpenes, phenolic acids, tannin, mucilage, pectin and sugar. They possess diuretic, diaphoretic, mild anti-inflammatory, and antiviral properties. The flowers are used to treat colds and catarrh of the upper respiratory tract. The fruits are rich in flavonoids, anthocyanin glycosides, and essential oils. They possess antiviral, immunostimulatory, and antioxidant activity. The fruits are used to treat flu and to boost the immune system. The standardized extract, Sambucol, has been shown to inhibit hemagglutination and replication of influenza viruses in vitro and to reduce the severity and duration of flu in clinical trials. The flowers and fruits, including the Sambucol extract, are safe, and can be administered to infants and children.

BACKGROUND

Sambucus nigra L. is a member of the family, Adoxaceae, and its pharmacopeial name is *Sambuci flos* or *Sambuci fructus*. Common names include Elderflower, European Elder flower, Black Elder flower, and Elderberry. The parts used are the flowers, fruits, and leaves.

The tree grows to a height of between three and seven meters. The bark is light brown to gray and fissured. The leaves are narrow, dark green, and serrated. The flowers are small, white, and fragrant (Fig. 1). They grow in large clusters in flat, umbrella-like umbels. Each flower has five petals, five stamens, and one inferior ovary. The flowering tops are gathered in the wild and dried and separated by sorting them into individual flowers. The peduncles are discarded (2,3). The flowers have a characteristic odor and a mild sweet taste.

The fruits are round like a ball, 4 to 7 mm long (Fig. 2). The young fruits are green and they change from dark purple to black when they ripen. Each fruit contains one to three brownish, egg-shaped seeds. The fruits are sweet (slightly bitter), mucilaginous, and acidic with a characteristic aroma (4,5).

In **traditional medicine**, the flowers are used as a diuretic, laxative, and diaphoretic, as well as a gentle astringent for the skin. They are used as an infusion, a gargle for mouthwash, and for respiratory disorders such as coughs, colds, laryngitis, flu, and shortness of breath. Infusions and lotions from the flowers are used for clearing the skin of freckles and sunburn (1). The aqueous extract of the flowers is used for washing hands and face, as well as to whiten and soften the skin. Externally, herbal pillows are used for subduing swelling and inflammation. The fresh flowers are used for the distillation of Elder Flower Water, which is prepared made from 100 parts of fresh flowers and 500 parts of water. The product is a mild astringent and a gentle stimulant. It is used as a vehicle for eye and skin lotions (1). Vinegar prepared from the flowers of Elder is a known old remedy for sore throat.

CHEMISTRY AND PREPARATION OF THE PRODUCTS

The flowers contain:

- Flavonoids (up to 3%) composed mainly of flavonoid glycosides (astragalin, hyperoside, isoquercetin, and rutin) and free aglycones (quercetin and kaempferol) (Fig. 3)
- Cyanogenic glycosides (glycosides of 2-hydroxy-2-phenylacetone, such as sambunigrin)
- Triterpenes approximately 1% including α - and β -amyrin, oleanolic, and ursolic acids
- Essential oils up to 0.3%, including 66% fatty acids (mainly linoleic, linolenic, and palmitic acids), alkanes (7%) and more than 60 other constituents including ethers, oxides, ketones, aldehydes, alcohols, and esters
- Minerals (8–9%), mainly potassium (6)
- Chlorogenic acid (3%), glucosides of caffeic and ferulic acids
- Tannin, mucilage, pectin, and sugar (7,8)

The highest amount of rutin (1.9%) is present in the buds together with pectin (0.8%) and sugars (2.5%) (9).

Elder leaves contain essential oils (0.02%), fats (4.8%), resins (4.3%), ketoses (3.5%), aldoses (0.9%), chlorophyll (0.8%), tannins (0.4%), pectins (0.2%), xanthophylls (0.1%), carotenes (0.05%), sambunigrin (0.04%),

Figure 1 Flowers of *Sambucus nigra* L.

and rutin (0.02%), as well as pentacyclic hydroxy triterpenoids—oleanoic and ursolic acids (9).

The fruits (Elderberries) are rich in flavonoids, thiamine, riboflavin, vitamins B6, C, and P-complex (10). Like the flowers, they contain flavonoid glycosides and anthocyanin glycosides (such as chrysanthemin, sambucin, and sambucyanin). They also contain approximately 0.01% of

Figure 2 Berries of *Sambucus nigra* L.

Figure 3 Quercetin chemical structure.

essential oils. Present in the seeds are the cyanogenic glycosides including holocalin, prunasin, sambunigrin, and zierin (10).

Quantitative Standards: Total flavonoids: not less than 0.8% (calculated as isoquercetin). Foreign matter: not more than 10% pedicles and not more than 1% other foreign matter. Loss on drying: not more than 10%. Ash: not more than 10% (8).

Preparations and Dosage

Infusion: 2 to 4 g of flowers in 150 mL of boiling water; strain after 10 minutes. Take three times daily. One teaspoon ~1.5 g. **Liquid Extract** (1:1 in 25% alcohol): 2 to 4 mL, three times daily.

Tincture (1:5, 25% alcohol): 10 to 25 mL per day (11–13). Another source (14) reports that the tincture is prepared in 45% alcohol and the dosage is 5 to 8 mL per day. According to WHO, the tincture should be prepared with 25% alcohol (11).

Topical Use: Infusion of the flowers is used as a wash or compress for improving oily skin or acne, or for treating injured tissues. Tincture of 3 to 5 mL diluted in 240 mL of water can be used for the same purpose (14). There are lotion and cream formulations of the flower extracts also.

Use as Food: The flowers are used as flavor in numerous food products, including alcoholic and non-alcoholic beverages, frozen dairy desserts, candy, baked goods, and gelatins and puddings. The highest concentrations of flowers are known to be in nonalcoholic beverages (0.05%) (15).

Phytomedicines: The flowers are added to a variety of tea mixtures. Flower extracts are also present in antitussives, for example, Sinupret for sinusitis (8).

Branded Preparation: Sambucol[®], liquid formula contains 38% standardized liquid Elderberry extract 2:1 (10 mL, 1–4 times a day). Lozenge formula contains 130 mg standardized Elderberry dry extract (1–2 lozenges, 2–3 times a day).

PRECLINICAL AND CLINICAL STUDIES

The extracts of the Elder have antiviral, anticatarrhal, diaphoretic, diuretic, and topical anti-inflammatory properties. Accordingly, Elderberry is used for colds, feverish catarrhal complaints, cough, and bronchitis, as well as an expectorant for treatment of mild inflammation of the upper respiratory tract (11).

Pharmacokinetics

The pharmacokinetics and the bioavailability of Elder ingredients are not fully understood. One of the main controversies is whether the anthocyanins are absorbed intact or after they are metabolized in the gastrointestinal tract. Pharmacokinetic studies of Elderberry extract show that anthocyanins are absorbed and excreted in an intact form (16,17). In the first study, six healthy volunteers were given a single oral dose of 30 mL Elderberry extract (147.3 mg total anthocyanins) resulting in a fast urinary excretion of intact anthocyanins; the $t(1/2)$ value was reported to be 1.74 hour (16). In another study, it was shown that Elderberry anthocyanins can be detected unchanged in the plasma, and most of them were excreted within four hours after consumption (17). A subsequent study with seven volunteers revealed similar results; however, it was concluded that the low urinary excretion of unchanged anthocyanins may indicate that a large portion of them are metabolized before entry into the circulation (18). All studies mentioned in this article (18) agree that oral administration of anthocyanins display first-order, one-compartment kinetics.

Activities and Indications

As already mentioned, the different parts of the plant are used for the treatment of a variety of ailments. The following discussion is therefore divided according to the individual plant parts and their respective indications.

Flowers

Human studies have not been documented for Elder flowers.

Anti-inflammatory Effects

Elder flowers alleviate inflammation and pain in carrageenan-induced rat paw edema. An alcohol extract of the flowers was administered intragastrically one hour before the administration of carrageenan (100 mg/kg) (19). The control drug, indomethacin (5 mg/kg body weight) inhibited carrageenan-induced rat paw edema by 45%, while the extract of Elder flowers inhibited inflammation by 27% (19).

Elder flowers were found to inhibit the proinflammatory activity of major virulence factors from the periodontal pathogens, *Porphyromonas gingivalis* and *Actinobacillus actinomycetemcomitans* (20). Inhibitory effects on the biosynthesis of the inflammatory cytokines such as interleukin-1-alpha, interleukin-1-beta, and tumor necrosis factor alpha (TNF-alpha) were shown in vitro with an extract of flowers at a concentration of 30 µg/mL (21).

Antiviral Effects

An infusion made from flowers of *S. nigra*, aerial parts of *Hypericum perforatum*, and roots of *Saponaria officinalis* has shown antiviral activity against influenza types A and B both in mice and in vitro, as well as against herpes simplex virus type 1 (22).

Diuretic Effects

Intragastric administration of an infusion of the flowers (20 mL/kg body weight) or a potassium- and flavonoid-rich extract of the flowers had a diuretic effect in rats. Their

diuretic effect exceeded that of theophylline. The greatest activity was exhibited by extracts rich in potassium and flavonoids (23). It has also been stated that flavonols could also contribute to the diuretic action (12).

Diaphoretic Effects

Although the diaphoretic effect of the flowers is well known, the mode of action is not fully understood. It is possible that flavonoids and phenolic acids are involved (12). It has been suggested that Elder flowers increase the response of sweat glands to heat stimuli (diaphoresis) in healthy subjects (8,11).

Fruits (berries)

Antiviral Effects

Though there are far fewer studies on the berries than on the flowers, in recent years there has been an increase in the awareness of the benefits of the Elder fruit among scientists. Most of the scientific studies on Elderberries, including in vivo clinical studies, were performed using a standardized preparation called Sambucol. In vitro studies have shown a reduced hemagglutination and inhibition of replication of types A and B human influenza viruses including human H1N1 (Swine flu), as well as of animal strains including a type A turkey influenza virus (24). One study examined the effects of Sambucol against four strains of Herpes Simplex Virus-1 (HSV-1) (25), two of which were acyclovir-resistant. The viral replication was completely inhibited in all four strains, irrespective of whether the cells were preincubated with the extract, simultaneously incubated with extract, or the extract was added 30 minutes after viral adsorption to cells.

A direct binding assay established in vitro that flavonoids from the elderberry extract bind to H1N1 virions and, when bound, block the ability of the viruses to infect host cells. The flavonoids were identified as, 5,7, 3',4'-tetra-O-methylquercetin and 5,7-dihydroxy-4-oxo-2-(3,4,5-trihydroxyphenyl)chroman-3-yl-3,4,5-trihydroxycyclohexanecarboxylate. This work was performed in 2007 on the H1N1 strain obtained from the American Type Culture Center and not on the novel 2009 H1N1 strain (26).

It is interesting to note that elderberry concentrates have no antibacterial effect and exhibited even a slight stimulatory effect on the growth of *Staphylococcus aureus* and *Saccharomyces cerevisiae* (27).

The above-standardized extract (Sambucol) was also tested in two double blind, placebo-controlled clinical trials. The first consisted of individuals with confirmed influenza B experiencing flu symptoms. Patients were randomized to receive either Sambucol or placebo (a liquid of the same color and texture as the Sambucol) daily for three days. A significant improvement in symptoms, including fever was experienced by 93.3% of the Elderberry-treated group within two days. In contrast, 91.7% of the placebo group showed a similar improvement only after day six. Complete cure was achieved within two to three days in approximately 90% of the Elderberry-treated group, and within six days in the placebo group. Higher levels of influenza antibodies were detected in patients receiving Elderberry than those receiving the placebo, suggesting

an enhanced immune activity (24). A second clinical trial (conducted by scientists from the University of Oslo) with 60 adults also demonstrated the safety and efficacy of the standardized Elderberry syrup in the treatment of influenza and its symptoms (28). Patients with either influenza type A or type B were given 15 mL of Sambucol or a placebo four times per day. Treatment was initiated within 48 hours of the onset of symptoms and continued for five days. The global evaluation scores (symptoms and overall wellness scores combined) for the Elderberry-treated group showed a pronounced improvement after a mean of 3.1 days as compared to 7.1 days for the placebo group. A larger number of patients in the control group resorted to a "rescue medication" such as paracetamol as compared to the treatment group. Both studies concluded that patients exhibiting flu symptoms and treated with Elderberry standardized extract recovered significantly faster than patients in the control group. As the authors note in their report, these findings need to be confirmed in a larger study.

Another placebo-controlled study indicated that Sambucol given as prophylactic to a group of chimpanzees accumulated over a period of six months reduced the flu-like symptoms to 12 days as compared to 39 days in the control group (total of ten chimpanzees randomized into two equal groups) (29).

Immune Enhancement

Results from two in vitro studies demonstrated that Sambucol upregulates cytokine release (30,31). Both studies used blood-derived monocytes and examined the concentration of four inflammatory cytokines (IL-1 β , IL-6, IL-8, TNF- α) and one anti-inflammatory cytokine (IL-10), in response to various Elderberry (Sambucol) formulations and control syrups (other branded preparations based on Echinacea and Propolis). A 1.3- to 6.2-fold increase in cytokine production was observed compared to control (31). It was concluded that the standardized Elderberry extract activates the healthy immune system and may possess immunoprotective or immunostimulatory effects when administered to patients with various diseases.

Antioxidant Activity

The berries are rich in anthocyanins, which serve as natural antioxidants. Ginsburg et al. (32) suggested that the unique composition of the constituents results in antioxidants, which are more resistant to oxidation. Because it has been observed that anthocyanin glycosides are indeed absorbed in humans (see pharmacokinetics), it is possible that Elderberry extracts containing anthocyanins may be a significant source of antioxidants.

Plasma antioxidant capacity and total phenolics were significantly increased one hour after ingestion of 400 mL of Elderberry juice (33), while heating over six hours at 95°C caused a decline of the trolox equivalent antioxidant capacity due to colorless degradation following thermal exposure (34). Another in vitro study demonstrated that Elderberry derived anthocyanins could be incorporated into the membrane and cytosol of endothelial cells (human aortic) and thus increase protection against oxidative stress (35).

Anticarcinogenic Activity

An aqueous acetone extract of the berries from cultivated *S. nigra* was fractionated and tested in a range of assays that gauge the anticarcinogenic potential. *S. nigra* fruits demonstrated significant chemopreventive potential through strong induction of quinone reductase and inhibition of cyclooxygenase-2, which is indicative of anti-initiation and antipromotion properties (36). Elderberry anthocyanins played a major role in chemoprotection and could inhibit the growth of a human colorectal adenocarcinoma (HT29) cell line (37).

Leaves

While the flowers and leaves are the plant parts mainly used, intraperitoneal administration of the unsaponifiable fraction (the fraction not soluble in water after saponification of total extract in KOH) of the leaves to mice moderately enhanced phagocytosis at a dose of 0.5 mL/animal (38).

Safety

The majority of safety issues refer to the presence of the cyanogenic glycoside sambunigrin, which may be hydrolyzed in various plant parts to free hydrogen cyanide. Various sources state that the ripe fruits are edible without causing harm and are frequently used as additives for various foods. The safety of the standardized Elderberry extract preparation, Sambucol was demonstrated in a clinical study (28), where it was concluded that this Elderberry extract is safe and can be administered to the whole population, including infants and children.

One study reported type I allergy to proteins of *S. nigra* (39) after inhalation of pollens, and the authors suggested that oral administration of flowers or berries could also induce allergies. On the contrary, Elderberry and Elder flowers were suggested to be beneficial for allergic symptoms and reduce nasal congestion and other upper respiratory discomforts.

Contraindications

To the best of our knowledge there are no published data showing that there are contraindications in the use of Elderberry.

Use During Pregnancy and Lactation: There are no known restrictions for pregnant or lactating women (6). Some authors propose that the use of Elder flowers during pregnancy should be avoided due to lack of toxicity data. However, there is no information available on impairment of fertility or teratogenic effects (7,40).

Drug/Herb Interactions

There are no reported drug/herb interactions with other plants or medications. Theoretically, since the Elderberry may exhibit a diuretic and a laxative effect, caution should be exercised when taken for a long time concomitantly with diuretics or with drugs that interact with diuretics and laxatives.

Side Effects

There have been no reported side effects from Elder flower preparations. The most common side effect for Elderberries quoted in the literature is the diuretic and laxative

effect (41). Elder preparations from unripe berries (as well as from other plant parts) can induce toxic effects in humans due to poisonous cyanogenic glycosides. Effects of cyanide, also known as hydrocyanic acid, on humans include nausea, vomiting, and diarrhea as well as central nervous system and respiratory depression, and general lethargy.

REGULATORY STATUS

Both flowers and berries are classified as GRAS (generally recognized as safe).

Elder is listed by the Council of Europe in Categories N1 (refers to the fruit and indicates that there are no restrictions on quantities used) and N2 (41). In the list of plants in the French official bulletin of drugs based on plants, instructions for the submission of registration (AMM allég), Elderberries belong to category one for which no toxicological studies are needed (42). The berries of Elder are rated by the American Herbal Products Association as Class 1, meaning "herbs which, when used appropriately, can be consumed safely without specific use restrictions" (43).

Eleuthero

Josef A. Brinckmann

INTRODUCTION

Eleuthero is obtained from *Eleutherococcus senticosus* (Rupr. et Maxim.) Maxim. [syn: *Acanthopanax senticosus* (Rupr. et Maxim.) Harms], a member of the ivy family (Araliaceae). Preparations of the dried root and rhizome or stems have an approximate 2,000-year history of use in Traditional Chinese Medicine (TCM), generally administered as a component of complex herbal mixtures prepared by aqueous decoction. For the related Japanese Kampo system of medicine, it is the rhizomes, often with root, that are specified. Dried aqueous-ethanolic extracts in tablet form and liquid extracts for intravenous drip are also used today as monopreparations in Oriental medical practice. Starting in the 1940s, scientists in the former Soviet Union began intensive pharmacological and clinical research on eleuthero preparations whereby the “adaptogen” concept was developed and tested over the following decades. It was proposed that an adaptogen is an innocuous substance, relatively free of side effects, has nonspecific action, increases resistance to a wide range of environmental or other physical stressors, and may have a normalizing action in the body irrespective of a diseased state. In 1962, the first eleuthero preparation received marketing authorization in the former Soviet Union. A quality standards monograph then became official in the *State Pharmacopoeia of the Union of Soviet Socialist Republics*. By 1975, eleuthero preparations entered European commerce and in 1991 the German health authority published a positive monograph for marketing authorization and labeling of eleuthero medicinal products. A corresponding quality standards monograph then entered the *German Pharmacopoeia* (now superseded by the *European Pharmacopoeia* eleuthero monograph). In 2008, on the basis of comprehensive expert committee reviews of the literature to date, the European Medicines Agency (EMA) and Health Canada each published their own final eleuthero monographs, which now have relevance for licensing or registration of eleuthero traditional herbal medicinal products (THMP) in EU Member States or eleuthero Natural Health Products (NHP) in Canada, respectively. EMA permits registration of eleuthero THMPs on the basis of evidence of traditional use only. Health Canada also permits licensing of eleuthero preparations on the basis of efficacy evidence for use in herbal medicine practice. As of 2009, the Canadian Licensed Natural Health Products Database listed details on over 100 eleuthero-containing NHPs. Although eleuthero is now regulated as an active substance for use in licensed, listed, or registered medicinal products in many

countries including Australia, Canada, China, European Community, Japan, and Russian Federation, since 1994 it has been regulated as a dietary supplement component in the United States. In the preamble of the Food and Drug Administration’s (FDA) final rule on statements made for dietary supplements concerning their effect on the structure or function of the body, the agency provided examples of potentially acceptable structure/function claims including “energizer,” “rejuvenative,” “revitalizer,” and “adaptogen,” all of which could apply to eleuthero dietary supplements depending on the level of evidence that the notifying firm compiles in its substantiation file. Although numerous preclinical and clinical studies have been carried out, aiming to prove the nonspecific adaptogen concept, the totality of evidence remains inconclusive to substantiate the efficacy of eleuthero preparations for any specific conditions. A significant amount of newer research involves preparations of eleuthero in combination with, or compared against, one or more other substances also proposed to exhibit adaptogenic action, among other combinations for treatment of various conditions ranging from upper respiratory tract infections to osteoarthritis.

BACKGROUND

The genus *Eleutherococcus* includes 38 species that occur in Eastern Asia, 18 of which occur in China (14 endemic). Known in Chinese medicine as *ci wu jia*, as *shi go ka* in Japanese medicine and as *eleuterokokk koljučij* in Russian, the species that is the subject of this article, *E. senticosus*, occurs in scrub fields, forests, roadsides, and valleys below 2000 m in China (Provinces of Hebei, Heilongjiang, Jilin, Liaoning, N Shaanxi, Shanxi, and Sichuan), Japan (Hokkaido Island), the Korean Peninsula, and the Russian Far East (Siberia). Other related species also used medicinally in China include *xi ci wu jia* [*E. setulosus* (Franchet) S.Y. Hu], *xi zhu wu jia* [*E. nodiflorus* (Dunn) S.Y. Hu], *wu geng wu jia* [*E. sessiliflorus* (Rupr. et Maxim.) S.Y. Hu], *lun san wu jia* [*E. verticillatus* (G. Hoo) H. Ohashi], *kang ding wu jia* [*E. lasiogyne* (Harms) S.Y. Hu], and *bai le* [*E. trifoliatus* (L.) S.Y. Hu] (1). Japanese researchers have determined that at least three different species are commercially traded interchangeably under the same common name. An analysis of the nuclear ribosomal DNA internal transcribed spacer sequence of eleuthero products available in the Japanese and Chinese markets found that only about

70% of all samples were made from the correct official species (*E. senticosus*). Quantitative determination of three marker compounds, eleutheroside B, syringaresinol diglucoside, and isofraxidin by ultra performance liquid chromatography/mass spectrometry showed that eleutheroside B and isofraxidin are specific to the correct source plant (2). Inaccurate identification of investigational products has implications for outcomes of laboratory and clinical research.

The eleuthero material of commerce is mainly collected from wild populations in the People's Republic of China and Russian Federation, with increasing commercial quantities being produced under regulations for organic certification according to a sustainable wild-crop harvesting practice standard. In China, some of the supply is also cultivated in fields and mountain terraces. Eleuthero is harvested in the spring or autumn, washed clean, dried and supplied as broken pieces of root and rhizome or stem. The rhizome is knotty, of irregular cylindrical shape, 15 to 30 cm long, and 1.4 to 4.2 cm in diameter. The root is cylindrical, mostly tortuous, 3.5 to 12 cm long, and 0.3 to 1.5 cm in diameter. The stems are long and cylindrical, varying in length, and 0.5 to 2 cm in diameter (3).

Listed in China's earliest materia medica published during the Han Dynasty (206 BC–AD 220), the *Shen Nong Ben Cao Jing* (Herbal Classic of the Divine Plowman), eleuthero continues to be used in TCM generally as a component of complex formulations but also as a monopreparation. In TCM theory, eleuthero acts to "replenish *qi* (vital energy) and invigorate the *spleen*" and "nourish the *kidney* and anchor the mind". The Chinese Pharmacopoeia Commission indicates the use of eleuthero preparations for treatment of lassitude, anorexia, aching pain in the lower back and knees, insomnia and dreamfulness due to *yang deficiency* in the *spleen* and *kidney*. *Yang deficiency* is a general term for lack of physiological energy of life with diminished functions (3).

In 1947, Russian pharmacologist Prof. Nikolai Vasilievich Lazarev, M.D., first proposed the term "adaptogen" to classify substances such as eleuthero that may act to increase "nonspecific" resistance to adverse influences to organism and stress (as a state of threatened homeostasis). In the following decades, antistress effects of eleuthero were investigated in animal experiments and human trials in the Soviet Union. A student of Dr. Lazarev, pharmacologist Prof. Israel I. Brekhman, M.D., defined the general pharmacodynamic characteristics of an adaptogenic substance and was responsible for introducing eleuthero preparations into Russian medical practice. The first eleuthero product was granted marketing authorization for clinical use in the former Soviet Union in 1962 (4,5). In 1978, the first eleuthero products were notified to the German health authority and in 1991, the German Commission E [now part of the Federal Institute for Drugs and Medical Devices (BfArM)] published a positive monograph. The approved indications were for use as a tonic for invigoration and strengthening in cases of fatigue and debility or declining capacity for work and concentration, as well as during convalescence. In 2003, BfArM published a more detailed monograph providing patient information text for labeling of registered eleuthero medicinal products in Germany (6). As a result of the European Union

Directive on Traditional Herbal Medicinal Products, which came into force in 2004, EMEA's Committee on Herbal Medicinal Products was charged with establishing Community Herbal Monographs for the registration and authorization of herbal medicinal products in EU Member States. The Committee on Herbal Medicinal Products conducted a comprehensive review of the scientific literature on eleuthero, assessing more than 300 papers, and in 2008 published a final monograph that indicates the therapeutic use of eleuthero as a THMP for symptoms of asthenia such as fatigue and weakness (7). The quality of eleuthero used as an active substance of a THMP must comply with the corresponding pharmacopeial quality standards monograph *Eleutherococci radix* PhEur (8).

In the United States, with the passage of the *Dietary Supplement Health and Education Act of 1994* (DSHEA), eleuthero preparations became regulated as dietary supplement products rather than as medicinal products. The FDA has provided examples of potentially acceptable structure/function statements that could be applicable to eleuthero dietary supplements (e.g., energizer, rejuvenative, revitalizer, or adaptogen) (9). In Canada, following the enactment of the *NHP Regulations*, which came into effect in 2004, the Natural Health Products Directorate (NHPD) was charged with developing the *NHPD Compendium of Monographs*, which applicants can reference in support of the safety and efficacy of an NHP as part of their product license application. In 2008, Health Canada's NHPD published its final monograph on eleuthero for compendial product license applications. The quality of eleuthero used as an active ingredient of an NHP may comply with the monograph of either the *European Pharmacopoeia* (*Eleutherococcus* PhEur) or *United States Pharmacopoeia* (*Eleuthero* USP) (10).

CHEMISTRY AND PREPARATION OF PRODUCTS

Over 35 compounds have been identified so far, but it is not yet clear which constituents or groups of constituents are most responsible for the effects of eleuthero. Because it appears that a complex mixture of constituents are responsible for the biological effects, the defined eleuthero preparation in its entirety must be regarded as the active substance. Certain constituents such as eleutherosides B and E are generally accepted to contribute to the therapeutic activity but are not responsible for the full therapeutic effect. As such, these constituents are used for control purposes and are defined as "active markers." Therefore it is important for researchers and product manufacturers to select eleuthero materials that test in conformance with all of the qualitative and quantitative standards of a specific pharmacopeial monograph for batch-to-batch uniformity and reproducible results. In any case, eleutherosides cannot be assigned to a particular compound class but instead belong to a variety of chemical groups (including lignans, phenylpropanes, coumarins, saponins, sterols, and sugars). Most eleutherosides were described under different names before they were isolated from *E. senticosus*. Although it has been suggested that use of the term "eleutherosides" should be discontinued, in order to prevent the impression that these substances belong to the

Table 1 Summarized Comparison of Eleuthero Pharmacopoeial Standards

Standard	JP XV	PhEur 6	PPRC 2005	USP 32-NF 27
Definition	Dried rhizomes often with root	Dried, whole or cut underground organs	Dried root and rhizome or stem	Dried rhizome and roots
Content	No standard (eleutheroside B present by HPLC)	Min 0.08% for the sum of eleutherosides B and E (by HPLC)	Min 0.05% of eleutheroside B (by HPLC)	Min 0.08% for the sum of eleutherosides B and E (by HPLC)
ID tests:	Macroscopic Microscopic Organoleptic HPLC test	Macroscopic Microscopic TLC test	Macroscopic Microscopic Organoleptic TLC test	Macroscopic Histology TLC test
Foreign matter	No standard	Max 3%	No standard	Max 3.0%
Loss on drying	Max 13.0%	Max 10.0%	Max 10.0%	Max 14.0%
Total ash	Max 6.0%	Max 8.0%	Max 9.0%	Max 8.0%
Acid-insoluble ash	Max 1.0%	No standard	No standard	No standard
Ethanol-soluble extractives	Min 2.5%	No standard	Min 3.0%	No standard
Water-soluble extractives	No standard	No standard	No standard	Min 4.0%

Abbreviations: JP XV, Japanese Pharmacopoeia, 15th edition 2007; PhEur 6.0, European Pharmacopoeia, 6th edition 2009; PPRC 2005, Pharmacopoeia of the People's Republic of China, 2005 English Edition; USP 32-NF 27, United States Pharmacopoeia 32nd revision National Formulary 27th edition 2009.

same compound group, use of this term continues in official compendia (11). Table 1 provides a summarized comparison of quality standards for eleuthero as published in currently valid editions of the *Japanese Pharmacopoeia* (JP) (12), *European Pharmacopoeia* (PhEur) (8), *Pharmacopoeia of the People's Republic of China* (PPRC) (3), and *United States Pharmacopoeia-National Formulary* (USP-NF) (13).

According to the 2008 EMEA assessment report, eleuthero root is characterized by the coexistence of pentacyclic and tetracyclic triterpenoidal saponins and their prosapogenins, lignans, coumarins, phenylcarbonic acids, and xanthenes. The main constituents are phenyl propane compounds (eleutheroside B: 0.5%, chlorogenic acid, coniferyl aldehyde and its glucoside, caffeic acid derivatives); lignans (eleutheroside E: 0.10%, eleutheroside B₄: 0.023%; coumarins (isofraxidin and its O-glucoside); triterpene saponins (2-protoprimulagenin A glycoside: 0.125%). Other constituents include steroids, carbohydrates, and immunologically active polysaccharides (heteroglycans and eleutherans) (14). As active markers, both the PhEur and USP, respectively, require that dried eleuthero root contain not less than 0.08% of the sum of eleutheroside B (C₁₇H₂₄O₉; M_r 372.37) and eleutheroside E (C₃₄H₄₆O₁₈; M_r 742.7), as determined by the High Performance Liquid Chromatography (HPLC) methods specified in the monographs. But according to the PPRC, the dried root and rhizome or stem must contain not less than 0.050% of "syringoside" (C₁₇H₂₄O₉; M_r 372.37) as determined by HPLC. Syringoside, a phenylpropanoid glycoside, is also referred to as "syringin" and/or "eleutheroside B" [chemical name: β-D-Glucopyranoside, 4-(3-hydroxy-1-propenyl)-2,6-dimethoxyphenyl]. Eleutheroside E is a lignan also referred to as "syringaresinol diglucoside" [chemical name: β-D-Glucopyranoside, (tetrahydro-1H,3H-furo(3,4-c)furan-1,4-diyl)bis(2,6-dimethoxy-4,1-phenylene)bis-].

Preparations of eleuthero are defined in official pharmacopoeial monographs and therapeutic compendia. Table 2 provides descriptions of compendial eleuthero preparations with details on their specified mode of administration and posology.

PRECLINICAL STUDIES

Numerous in vivo studies have been carried out designed to evaluate the adaptogenic response to a range of induced adverse conditions such as stress, immobilization, or chemical challenges in animal models using a 33% ethanolic extract of eleuthero root. For summaries of the extensive experimental pharmacology data, see eleuthero monographs in WHO Vol. 2 2002 (15) and ESCOP 2nd ed. 2003 (16).

Ethanolic extract of eleuthero stem bark administered with a feeding tube to Dawley rats (100 mg/kg body weight) caused c-Fos accumulation in both the supraoptic nuclei and paraventricular nuclei, which regulate stress response. Only the caudal regions in the nucleus of the solitary tract, a locus innervating both the supraoptic nuclei and paraventricular nuclei, were activated. This neuroanatomical pattern suggests a possible involvement of these stress-related brain loci in association with eleuthero ingestion (17). Liquid extract of eleuthero root combined with cadmium chloride given to mice in a drink solution led to a significant decrease of cadmium concentration in the blood and liver. Eleuthero decreased the cadmium-induced mitotic and apoptotic activity of liver cells (18). Intraperitoneal administration of eleuthero root extract prior to injection of lipopolysaccharide and D-galactosamine in mice significantly improved survival rate. Eleuthero pretreatment appeared to protect mice against lipopolysaccharide and D-galactosamine-induced endotoxic shock involving inhibition of NF-kappaB activation, which caused downregulation of TNF-α and involved upregulation of interleukin-10 (19).

CLINICAL STUDIES

This article discusses mainly the results of controlled clinical trials involving monopreparations of eleuthero published between 1990 and 2009 that are available in the English language literature. Many other trials published from the 1960s to the present are available only in the Chinese or Russian literature. English language abstracts

Table 2 Compendial Eleuthero Preparations, Mode of Administration and Posology

Preparation	Definition	Mode of administration	Posology
Eleuthero Dry Aqueous Extract EMA	Dry extract prepared by extracting with water from <i>Eleutherococcus</i> PhEur; drug-to-extract ratio range is between 15:1 and 17:1	Oral use in capsules or tablets	90–180 mg; may be taken in 1–3 doses daily
Eleuthero Dry Ethanolic Extract EMA	Dry extract prepared by extracting with ethanol and water from <i>Eleutherococcus</i> PhEur (ethanol 28–70% v/v)	Oral use in capsules or tablets	Daily dose corresponding to 0.5–4 g dried root; may be taken in 1–3 doses daily
Eleuthero Herbal Tea EMA	Comminuted <i>Eleutherococcus</i> PhEur supplied in bulk form or packed in filter sachets. Contains min. 0.08% sum of eleutherosides B and E	Oral use. Pour 150 mL boiling water over 0.5–4 g cut root. Infuse for 10–15 min	150 mL of tea infusion divided in 1–3 doses daily
Eleuthero Infusion NHPD	Comminuted Eleuthero USP or <i>Eleutherococcus</i> PhEur supplied in bulk form or packed in filter sachets. Contains min. 0.08% sum of eleutherosides B and E	Oral use. Pour 150 mL boiling water over 2–3 g cut root. Infuse for 10–15 min	150 mL of tea infusion daily
Eleuthero Liquid Extract EMA/NHPD	Hydroalcoholic liquid preparation prepared from <i>Eleutherococcus</i> PhEur; drug-to-extract ratio 1:1	Oral use liquid in dropper bottle	2–3 mL daily; may be taken in 1–3 doses
Eleuthero Solid Extract NHPD	See Powdered Eleuthero Extract USP	Oral use in capsules or tablets	0.065–0.195 g daily
Eleuthero Tincture EMA and/or NHPD	Alcoholic liquid preparation prepared by maceration or percolation from <i>Eleutherococcus</i> PhEur; drug-to-extract ratio 1:5	Oral use liquid in dropper bottle	10–15 mL; may be taken in 1–3 doses
Extractum Acanthopanax Senticosi PPRC	Soft extract prepared by extracting with water or ethanol from <i>Radix et Rhizoma seu Caulis Acanthopanax Senticosi</i> PPRC; drug-to-extract ratio 20:1. Contains min. 0.5% of syringoside, min. 45% water-soluble extractive, max. 30% water	Oral use in tablets; Tabellae Acanthopanax Senticosi PPRC	Extract: 0.3–0.45 g, 3 times daily Tablets: 2–3 twice daily
Powdered Eleuthero EMA	Powdered from <i>Eleutherococcus</i> PhEur. Contains min. 0.08% sum of eleutherosides B and E	Oral use in capsules or tablets	0.75–3 g daily; may be taken in 1–3 doses
Powdered Eleuthero Extract USP	Dry extract prepared from Eleuthero USP, extracted with hydroalcoholic mixtures; drug-to-extract ratio range is between 13:1 and 25:1. Contains min. 0.8% sum of eleutherosides B and E	Oral use in capsules or tablets	See Eleuthero Solid Extract NHPD

Abbreviations: EMA, European Medicines Agency; NHPD, Natural Health Products Directorate; PhEur, European Pharmacopoeia; PPRC, Pharmacopoeia of the People's Republic of China; USP, United States Pharmacopoeia.

for some of these are available but often lack essential details on study design and composition of investigational product. Most of the older studies were carried out without controls. Furthermore, the trend for much of the recent clinical research has been to evaluate the effects of polypreparations that contain eleuthero extract as just one of the active components or to evaluate the effects of concomitant administration of eleuthero with other herbal preparations. A review of clinical trials using eleuthero-containing complex mixtures is outside of the scope of this article. Table 3 summarizes recent (1990–2009) clinical studies involving monopreparations of eleuthero root or leaf. Table 4 provides a brief description of eleuthero-containing polypreparations that are undergoing clinical and laboratory research.

In a randomized controlled trial, Lee et al. (2008) investigated the effects of freeze-dried eleuthero leaf extract plus calcium versus calcium (control) on serum lipid profiles, biomarkers of oxidative stress, and lymphocyte DNA damage in postmenopausal women over a six-month period. There were significant decreases ($P < 0.001$) in serum LDL (127.54 ± 29.79 mg/dL versus 110.33 ± 22.26 mg/dL)

and the LDL/HDL ratio (2.40 ± 0.65 vs. 2.11 ± 0.58). Protein-carbonyl levels and lymphocyte DNA damage also decreased significantly ($P < 0.001$ and $P < 0.05$, respectively) (20). In a randomized, double-blind comparative trial, Weng et al. (2007) investigated the effects of an aqueous-ethanolic dry extract of eleuthero root plus lithium versus fluoxetine plus lithium in adolescents with bipolar disorder. No significant differences were seen. The response rate between the eleuthero and fluoxetine groups was similar (67.6% vs. 71.8%) as was the remission rate between both groups (51.4% vs. 48.7%) (21). Hartz et al. (2004) found no significant difference between eleuthero root and placebo after two months of treatment in volunteers with chronic fatigue syndrome (22). In a randomized, double-blind, placebo-controlled trial, Cicero et al. (2004) investigated the effects of eleuthero root dry extract in elderly hypotensive volunteers on health-related quality-of-life parameters. After four weeks, there were higher scores in social functioning ($P = 0.02$) scales but these differences did not persist to the eight-week period (23). Arushanian and Shikina (2004) investigated the effects of chronic administration of an ethanolic fluidextract

Table 3 Controlled Clinical Studies with Eleuthero Preparations 1990–2009

Reference	Duration	Number of patients	Preparation	Dosage	Comparison treatment
(20)	6 mo	40	Eleuthero leaf freeze-dried extract	2 × 500 mg t.i.d. + 500 mg calcium	Calcium
(21)	6 wk	76	Eleuthero root ethanolic dry extract	250 mg t.i.d. + 250 mg lithium b.i.d.	Fluoxetine or Lithium
(22)	2 mo	76	Eleuthero root powder	4 × 500 mg/day	Placebo
(23)	8 wk	20	Eleuthero root dry extract	300 mg/day	Placebo
(24)	1 mo	27	Eleuthero root liquid extract	20 drops b.i.d.	Placebo
(25)	30 days	45	Eleuthero root liquid extract	2 vials/day	Placebo
(26)	8 wk	47	Eleuthero root extract injection	Not known	Conventional treatment
(27)	6 wk	18	Eleuthero root 35% ethanolic extract	8 mL/day (4 g root equivalent)	Asian ginseng root extract or placebo
(28)	30 days	50	Eleuthero root fluidextract 1:1	25 drops t.i.d.	Echinacea herb juice preparation
(29)	7 days	9	Eleuthero root	1200 mg/day (for 7 days before trial)	Placebo
(30)	14 days	60	Eleuthero root extract injection	60–80 mL in 500 mL 0.9% saline by intravenous drip q.d.	Dextra-40 injection
(31)	3 mo each arm	24	Eleuthero root powder	1250 mg/day	Ginkgo leaf extract, vitamins or placebo
(32)	6 wk	20	Eleuthero root fluidextract	3.4 mL/day	Placebo
(33)	6 mo	93	Eleuthero root ethanolic dry extract	375 mg q.i.d.	Placebo
(34)	15 days	57	Eleuthero root extract injection	40 mL in 300 mL 5% dextrose injection by intravenous drip q.d.	Insulin and potassium chloride injection

of eleuthero root on light and color perception in healthy young adults without physical or ophthalmological disease. After one month, significant positive changes in eye sensitivity were observed in both morning and evening hours compared to placebo (24). In a randomized, double-blind, placebo-controlled trial, Facchinetti et al. (2002) concluded that 30 days of administration of eleuthero root liquid extract in healthy adults reduced some cardiovas-

cular responses to stress (25). In a randomized controlled trial, Ni et al. (2001), investigated the effects of eleuthero root extract injections on urinary albumin excretion and renal endothelin metabolism in type 2 diabetics with persistent microalbuminuria and normotension. After eight weeks of treatment, the levels of urinary albumin excretion as well as plasma and urinary endothelin lowered significantly ($P < 0.01$) in the eleuthero group with no

Table 4 Eleuthero-containing Polypreparations Undergoing Research

Eleuthero Combinations	Subject
With extract of andrographis herb [<i>Andrographis paniculata</i> (Burm. f.) Nees; Fam. Acanthaceae]	Treatment of upper respiratory tract infections
With extracts of andrographis herb, schisandra fruit [<i>Schisandra chinensis</i> (Turcz.) Baill.; Fam. Schisandraceae], and licorice root [<i>Glycyrrhiza glabra</i> L.; Fam. Fabaceae]	Treatment of familial Mediterranean fever
With extracts of Asian ginseng root [<i>Panax ginseng</i> C.A. Mey.; Fam. Araliaceae], Japanese aralia [<i>Aralia mandshurica</i> Rupr. & Maxim; Fam. Araliaceae], and rhodiola root [<i>Rhodiola rosea</i> L.; Fam. Crassulaceae]	Cardioprotective, inotropic, and antiarrhythmia properties
With extracts of Asian ginseng root, rhodiola root, and schisandra fruit	Impact on the level of energy, ability to work under stress, quality of life and wellbeing, in middle-aged working women
With extracts of echinacea [<i>Echinacea purpurea</i> (L.) Moench.; Fam. Asteraceae] and Malabar nut tree leaf [<i>Adhatoda vasica</i> Nees; Fam. Acanthaceae]	Treatment of acute upper respiratory tract infections
With tincture of maral root [<i>Rhaponticum carthamoides</i> (Willd.) Iljin; Fam. Asteraceae]	Effects on blood coagulation system during training in athletes
With aqueous-ethanolic dry extracts of maral root, rhodiola root, and schisandra fruit	Effects on cell-mediated and humoral immunity of patients with advanced ovarian cancer
With perilla fruit [<i>Perilla frutescens</i> (L.) Britt.; Fam. Lamiaceae]	Antiallergic effects
With rehmannia root [<i>Rehmannia glutinosa</i> Libosch. ex Fisch. & Mey.; Fam. Scrophulariaceae]	Postmenopausal osteoporosis
With aqueous extracts of rehmannia root and Tienchi ginseng [<i>Panax notoginseng</i> (Burk.) F.H. Chen; Fam. Araliaceae]	Knee osteoarthritis
With extracts of rhodiola root and schisandra fruit	Adjuvant in treatment of acute nonspecific pneumonia
With liquid extract of safflower [<i>Carthamus tinctorius</i> L.; Fam. Asteraceae]—as an injection	Treatment of traumatic intracranial hematoma

significant changes in the control group (26). In a comparative placebo-controlled study, Gaffney et al. (2001) investigated the effects of eleuthero root 35% ethanolic extract versus Asian ginseng root 35% ethanolic extract or placebo on competitive club-level endurance athletes engaged in normal in-season training. None of the immune system variables changed significantly nor showed any clear trend from pre- to post-test in any of the treatment groups. Furthermore, eleuthero increased rather than decreased hormonal indices of stress, suggesting a threshold of stress below which it increases stress response and above which it decreases stress response (27). Szolmicki et al. (2000) compared the effects of a eleuthero root fluidextract versus fresh pressed juice preparation of *Echinacea purpurea* herb [*Echinacea purpurea* (L.) Moench; Fam. Asteraceae] on cellular defense and physical fitness parameters. After one month, eleuthero influenced oxygen plateau by significantly increasing oxygen consumption during maximal physical exercise. Analysis of blood samples showed that the phagocytic activity of neutrocytes in the eleuthero group rose significantly and the number of neutrocytes actively participating in phagocytosis increased (28). Eschbach et al. (2000) found no significant differences in athletic endurance measurements between eleuthero and placebo groups at any steady-state time interval or during cycling time trials in highly trained male athletes (29). In a single-blind controlled trial, Han et al. (1998) evaluated the effect of eleuthero root liquid extract intravenous drip injection in treating acute cerebral infarction. After 14 days of treatment, the total effective rate of the eleuthero group (86%) was higher than the control group (50%). The nervous functional deficit score was significantly lower in the eleuthero group (9.96 ± 4.66) compared to control (13.56 ± 1.84). The proposed mechanism of action is ameliorating peroxidation in the brain and improving hypothalamic-pituitary-adrenocortical axis function (30). In a randomized, double-blind, placebo-controlled, crossover trial, Winther et al. (1997) compared the effects of eleuthero root, extract of ginkgo leaf [*Ginkgo biloba* L.; Fam. Ginkgoaceae], vitamins, and placebo on cognitive function in healthy middle-aged volunteers. After three months of treatment each (crossover) there were no changes in the D-2 concentration test results, whereas selective memory significantly improved during treatment with eleuthero ($P < 0.02$) versus placebo. The evaluation of 25 different visual analogue scales were also in favor of eleuthero ($P < 0.05$) versus placebo (31). In a six-week trial evaluating the effects of eleuthero root fluidextract on fatigue during submaximal and maximal aerobic exercise in athletes, Dowling et al. (1996) found no significant differences between eleuthero and placebo. It was concluded that ergogenic claims cannot be supported on the basis of these results (32). Williams (1995) investigated the effects of a standardized eleuthero root extract for immune protection against herpes simplex type 2 infection in patients with HSV-2. There were statistically significant results ($P = 0.0002$ to 0.0007) in the eleuthero group where 75% reported improvements in severity, duration, or frequency of herpes simplex type 2 attacks versus 34% in the placebo group. The investigator noted, however, that more than three months of treatment was required before optimum effects were observed, suggesting that eleuthero extract would be useful only for suppressive rather than episodic therapy (33). In a randomized controlled trial,

Shang et al. (1991) studied the effect of eleuthero root liquid extract intravenous drip injection in patients with coronary heart disease and myocarditis whose ventricular late potential (VLP) were positive. After 15 days of treatment, the rates of changing positive VLP into negative were 74.29% in the eleuthero group versus 34.6% in the insulin and potassium chloride control group ($P < 0.005$). The results appear to show that eleuthero injection may be an effective treatment in patients with positive VLP (34).

Efficacy

In a Cochrane Database of Systematic Reviews meta-analysis by Li et al. (2009) of West China Hospital, Sichuan University, the safety and efficacy of eleuthero preparations in patients with acute ischemic stroke was assessed. The researchers included randomized controlled trials comparing eleuthero with placebo or open control (no placebo) in patients with acute ischemic stroke. Of the 13 trials (962 participants) that met inclusion criteria, the outcome measure was the improvement of neurological deficit after treatment. Eleuthero was associated with a significant increase in the number of participants whose neurological impairment improved [risk ratio (RR) 1.22, 95% confidence interval (CI) 1.15 to 1.29]. The authors concluded, however, that the risk of bias in all the included trials was high, and therefore the data were not adequate to draw reliable conclusions about the efficacy of eleuthero in acute stroke. Much larger trials of greater methodological quality would be necessary (35).

Concerning efficacy evidence for an adaptogenic action, on the basis of a review of over 300 papers, the EMEA assessment report (2008) concluded that the principle of an adaptogenic action still needs further clarification and more preclinical and clinical studies. Although the EMEA is aware of the fact that numerous preclinical and clinical studies have been performed aiming to prove the adaptogenic concept, the clinical data have many limitations such as deficiencies in the description of inclusion and exclusion criteria, description of the investigational product, diagnosis, study design, and analysis etc. There is a wide range of clinical conditions that have been investigated and the number of patients has been very small in some studies. None of the studies would be sufficient to substantiate efficacy of eleuthero preparations in a clearly defined clinical condition. The total data available, however, are sufficient to justify further research into the adaptogenic concept (14). Individual researchers, however, continue to assert that good, albeit not strong, scientific evidence has been documented in trials in which eleuthero root preparations have been shown to increase endurance and mental performance in patients with mild fatigue and weakness (36).

Adverse Effects

According to the German BfArM (2003) and Canadian NHPD (2008), there are no known adverse reactions (6,10) although the EMEA assessment report (2008) states that there have been no systematic studies designed to detect adverse events. Individual case reports and other general evidence suggest that eleuthero preparations may cause insomnia in some people if taken too close to bedtime. Some cases of insomnia, as well as shifts in heart rhythm, tachycardia, extrasystoles, and hypertonia, were

reported in two clinical studies from the 1960s involving atherosclerotic patients. Two patients receiving high dosage eleuthero extract in a study involving 55 patients with rheumatic heart disease reported headaches, pericardial pain, palpitations, and elevated blood pressure. A small study involving 11 hypochondriac patients found that eleuthero liquid extract was well tolerated at a dosage range of 2.5 to 3.0 mL t.i.d. for 60 days, although some patients reported insomnia, irritability, melancholy and anxiety at dose levels of 4.5 to 6.0 mL (14). Thus, the EMEA final monograph (2008) lists the following potential undesirable effects: insomnia, irritability, tachycardia, and headaches with an unknown frequency of occurrence (7).

Interactions and Contraindications

There are no known or reported interactions with other substances. In a pharmacokinetic interaction study, Donovan et al. (2003) investigated the effects of standardized eleuthero root preparation (485 mg capsules containing 250 mg dry extract plus 235 mg powdered root) in 12 normal volunteers on the activity of cytochrome P450 CYP2D6 and CYP3A4. No significant differences were observed indicating that eleuthero at the generally recommended doses is unlikely to interact with coadministered medications that are primarily dependent on the CYP2D6 or CYP3A4 pathways for elimination (37).

Although the German BfArM monograph (2003) contraindicated the use of eleuthero preparations in cases of high blood pressure (6), according to a subsequent EMEA assessment report (2008) there is limited general evidence and very limited information from studies to support this contraindication. In two earlier clinical studies, it was recommended that the eleuthero extract investigational product should not be given to subjects with blood pressure in excess of 180/90 mm Hg. In any case, the EMEA final monograph included a contraindication of arterial hypertension (7,14). The final NHPD monograph (2008) also contraindicates eleuthero in cases of high blood pressure (10). Although there are no data suggesting the occurrence of general hypersensitivity to plants of the Araliaceae family, there is a theoretical potential of hypersensitivity reactions to eleuthero preparations. While there have been some studies involving pregnant women showing no teratogenic or embryotoxic effects, the general safety of using eleuthero preparations during pregnancy and lactation has not been fully established. Following the precautionary principle in the absence of sufficient data, a qualified health care practitioner should be consulted prior to use during pregnancy and lactation.

MECHANISM OF ACTION

Although the pharmacological effects of eleuthero preparations have been investigated extensively, the mechanism of action and the active compound(s) have not yet been fully identified (14). The general pharmacodynamic characteristics of an adaptogenic substance as originally defined by Dr. Brekhman are as follows:

- An adaptogen is almost nontoxic to the recipient.
- An adaptogen tends to be nonspecific in its pharmacological properties and acts by increasing the resistance of the organism to a broad spectrum of adverse biological, chemical, and physical factors.

- An adaptogen tends to be a regulator having a normalizing effect on the various organ systems of the recipient organism.
- The effect of an adaptogen is as pronounced as deeper are the pathologic changes in the organism.

According to a review paper by Panossian and Wikman (2009), the stress-protective effect of adaptogenic substances including eleuthero preparations is related to regulation of homeostasis via several mechanisms of action associated with the hypothalamic-pituitary-adrenal axis and the control of key mediators of stress response such as molecular chaperons (e.g., Hsp70), stress-activated c-Jun N-terminal protein kinase (JNK1), Forkhead Box O transcription factor DAF-16, cortisol, and nitric oxide (NO). According to this theory, the main point of action for an eleuthero preparation would appear to be upregulating and stress-mimetic effects on the "stress-sensor" protein Hsp70, which plays a role in cell survival and apoptosis. Hsp70 inhibits the expression of NO synthase II gene and interacts with glucocorticoid receptors directly and via the JNK pathway, thus affecting the levels of circulating cortisol and NO. Prevention of stress-induced increase in NO, and the associated decrease in ATP production, could result in increased performance and endurance. Adaptogen-induced upregulation of Hsp70 triggers stress-induced JNK-1 and DAF-16-mediated pathways regulating the resistance to stress, possibly resulting in enhanced mental and physical performance (36).

REGULATORY STATUS

Australia

Eleuthero root and preparations thereof are substances that may be used as active ingredients in Listed Medicines for supply in Australia (38). *Quality*: For active ingredients of listed medicines, the quality standard of the *British Pharmacopoeia* (BP) is the minimum standard that must be applied in its entirety. The PhEur and the USP, respectively, have also been adopted as additional default standards under the Therapeutic Goods Act. *Indications*: An adaptogenic herb traditionally used as a tonic to support the body during periods of exertion. Also useful during convalescence (39).

Canada

Eleuthero root is an NHP active ingredient, requiring premarketing authorization and product license issuance for over-the-counter human use. *Quality*: Must comply with the minimum specifications outlined in the current *NHPD Compendium of Monographs* (40). Pharmacopoeial standards currently accepted by the NHPD are the BP, PhEur, and USP (41). *Indications*: Dried root or preparations thereof (fluidextract, solid extract, tea infusion or tincture) used in Herbal Medicine as a tonic to help relieve general debility and/or to aid during convalescence, or to help improve mental and/or physical performance after periods of mental and/or physical exertion (10).

China

Eleuthero dried root and rhizome or stem (*Radix et Rhizoma seu Caulis Acanthopanax Senticosi*) is an active ingredient for use in Chinese medicinal preparations (e.g., aqueous

decoctions) and as starting material for the production of powdered ethanolic dry extract (*Extractum Acanthopanax Senticosi*) and tablets containing the extract (*Tabellae Acanthopanax Senticosi*). *Quality*: Eleuthero active ingredients of Chinese medicines must comply with the corresponding PPRC monograph. *Indications*: Hypofunction of the spleen and the kidney marked by general weakness, lassitude, anorexia, aching of the loins and knees, insomnia and dream-disturbed sleep (3).

European Community

Preparations of eleuthero (e.g., comminuted herbal substance for preparation of herbal tea, 1:1 liquid extract, 1:5 tincture, and dry extracts for solid dosage forms) are regulated as THMP requiring premarketing authorization and issuance of a traditional herbal registration for over-the-counter human use. *Quality*: Eleuthero for use in THMPs must comply with the PhEur monograph (*Eleutherococci radix*). *Indications*: Traditional herbal medicinal product for symptoms of asthenia such as fatigue and weakness (7).

Japan

Eleuthero rhizome is an active ingredient for use in Japanese Kampo medicine preparations. *Quality*: Eleuthero-active ingredients of Kampo medicines must comply with the JP monograph (*Eleutherococci senticosi Rhizoma*) (12).

Russian Federation

Eleuthero dried root and rhizome is an active ingredient for use in Russian medicinal products and as starting material for the production of a 33% ethanol extract (*Extractum Radicis et Rhizomatis Eleutherococcus*). *Quality*: Eleuthero-active ingredients must comply with the corresponding monograph of the *State Pharmacopoeia of the Union of Soviet Socialist Republics* (42).

United States

Preparations of eleuthero are regulated as dietary supplement products requiring FDA notification. The manufacturer of a eleuthero dietary supplement making a structure/function or general well-being claim must have substantiation demonstrating that the claim is truthful and not misleading (9). The dietary ingredient eleuthero or a dietary supplement containing it must identify the ingredient using the Latin binomial *E. senticosus* or the standardized common name "eleuthero." The term "Siberian ginseng" cannot be used (43). *Quality*: Dietary supplement quality standards monographs for eleuthero dried rhizome with roots, powdered eleuthero, and powdered eleuthero extract are official in the *United States Pharmacopoeia-National Formulary* (USP-NF) (13). The DSHEA amendments to the FD&C Act named *USP* and *NF* as the official compendia for dietary supplements. The amendments also provide that a dietary supplement may be deemed misbranded if it is covered by a monograph in an official compendium, is represented as conforming to this monograph, but fails to conform. Conformance to the *USP-NF* monograph is voluntary, however.

World Health Organization

A monograph for the oral use of powdered dried roots and rhizomes of *E. senticosus* (or equivalent preparations) is published in the *WHO Monographs on Selected Medicinal Plants* Volume 2. *Indications* (Medicinal Uses Supported by Clinical Data): As a prophylactic and restorative tonic for enhancement of mental and physical capacities in cases of weakness, exhaustion and tiredness, and during convalescence (15).

Ephedra

Anne L. Thurn with Joseph M. Betz

INTRODUCTION

Ephedra (Ma huang) is the common name for a herbal product used in traditional Chinese medicine. It comprises the aerial parts of three principal plant species: *Ephedra sinica* Stapf, *E. equisetina* Bunge, and *E. intermedia* var. *tibetica* Stapf (1–3). The plant is a natural source of the alkaloids (–)-ephedrine and (+)-pseudoephedrine (1).

GENERAL DESCRIPTION

Ephedra sinica Stapf is a low evergreen shrub with small scaly leaves. It flowers in June and July and produces fruit late in the summer (4). Approximately 45 to 50 species of ephedra have been described worldwide, including in the temperate and subtropical regions of Asia, Europe, and the Americas (2,5). Most of those native to North, South, and Central America, such as *E. nevadensis* (used to make Mormon tea), *E. trifurca*, and *E. antisiphilitica*, contain no alkaloids (5).

Most commercial uses of ephedra are based on its content of ephedrine, the main active constituent in the ephedra species known as *ma huang* (1). Alkaloid content increases as the plant matures, with peak concentrations in the fall (6). No ephedrine-type alkaloids are found in the roots, berries, or seeds of these plants, and the green upper parts of the stems contain significantly more alkaloids than the woody parts (6).

Traditionally, ephedra has been administered as a tea prepared by soaking 2 g dried aerial portions in 8 fl oz of boiling water for 10 minutes, ideally resulting in a content of 15 to 30 mg ephedrine. In commercial products, it is usually present in a formulation of powdered aerial portions or a dried extract (7). The ephedrine content of such products ranges from 12 to 80 mg per serving, with most being in the lower part of the range (8).

In the United States, ephedra was sold as a dietary supplement until April 2004 when the U.S. Food and Drug Administration (FDA) banned the sale of dietary supplements containing ephedrine alkaloids. As defined by Congress in the Dietary Supplement Health and Education Act, which became law in 1994, a dietary supplement is a product (other than tobacco) that is intended to supplement the diet; contains one or more dietary ingredients (including vitamins, minerals, herbs or other botanicals, amino acids, and other substances) or their constituents; is intended to be taken orally as a pill, capsule, tablet, or

liquid; and is labeled on the front panel as being a dietary supplement.

Ephedra-containing dietary supplements were most often promoted as weight loss aids or to improve energy levels and athletic performance, even though there is little or no evidence for their efficacy for these uses. Prior to the ban, a 1998 survey of more than 14,500 people, 18 years or older conducted in five states for the use of dietary supplements for weight loss reported that 7% used nonprescription products, while 1% consumed ephedra-containing preparations (9).

HISTORICAL USE

Ephedra has a history of more than 5000 years of medicinal use in China and India, where it has been used to treat cold, fever, flu, chills, headaches, edema caused by nephritis, nasal congestion, aching joints, coughing, and wheezing as well as to induce diuresis or perspiration (5,6). Evidence that its use predates even traditional Chinese and Indian medicine comes from the discovery of a species of ephedra found in a Neanderthal grave in Iraq dating from 60,000 B.C. (8). Analysis of the plants found in the grave indicated that they contained bioactive ingredients and were presumably used medicinally. There is documentation of its use by Discorides, the renowned Greek herbalist, in the 1st century and in Europe from the 15th to the 19th centuries (10). In the 1600s, Native Americans and Spaniards in the American Southwest used ephedra (the nonalkaloid-containing species) as a treatment for venereal disease (10).

Ephedrine, the principal active ingredient in most species, was first isolated in 1885 by Nagayoshi Nagai, a Japanese chemist trained in Germany (10). Other alkaloids, such as pseudoephedrine, norephedrine, and norpseudoephedrine, with similar but not identical properties, were subsequently found in various ephedra species (11).

Early studies on the pharmacological effects of ephedrine were conducted between 1888 and 1917, but it was not until the 1920s during studies of a variety of Chinese traditional herbs that ephedrine alkaloids became known to Western medicine. Ephedra, one of the herbs tested, gave significant results—an extract given intravenously to dogs resulted in a large increase in blood pressure (12). Subsequent publication of a series of studies on the pharmacological properties helped Western physicians understand its potential usefulness (11). These

experiments demonstrated that ephedrine had three advantages over epinephrine: it could be administered orally, was longer acting, and had a lower toxicity (3). As a result, the former alkaloid replaced the latter in the management of children with mild-to-moderate asthma. Subsequently, it became widely used as a nasal decongestant and central nervous system stimulant (4). Its ability to stimulate the central nervous system was recognized by the Japanese military, which administered it by injection to kamikaze pilots during World War II (8).

The herb ephedra was once recognized as an official drug in the United States, but widespread availability of synthetic ephedrine-type alkaloids virtually eliminated its clinical use (13).

CONSTITUENTS AND ACTIONS

Ephedra stems contain 0.5% to 2.5% (4) alkaloids, composed mainly of (–)-ephedrine and (+)-pseudoephedrine, with ephedrine content ranging from 30% to 90% of total alkaloid content depending on the source. The content of the various ephedra alkaloids varies in commercial preparations, but ephedrine and pseudoephedrine generally make up 90% to 100% (14). (–)-Ephedrine and five structurally related alkaloids, (+)-pseudoephedrine, (–)-*N*-methylephedrine, (+)-*N*-methylpseudoephedrine, (+)-norpseudoephedrine, and (–)-norephedrine, are responsible for the medicinal properties of these alkaloid-containing ephedra species (1). Ephedrine acts indirectly by stimulating α_1 -, α_2 -, β_1 -, and β_2 -adrenergic receptors to release norepinephrine from sympathetic nerve endings and directly as a β_1 -, β_2 -, and possibly β_3 -agonist (8,15,16). It promotes bronchodilation by stimulating β_2 -receptors in the lungs, which accounts for its effectiveness in treating bronchial asthma (12,16). However, its other adrenergic actions result in the generally undesirable effects of central nervous system stimulation including insomnia, irritability, hyperactivity (16), hypertension (14,17), and gastrointestinal symptoms (nausea and vomiting) (11). These side effects have led to the development of selective β_2 -agonists and the discontinuation of ephedrine use for bronchodilation.

Ephedrine increases heart rate and therefore cardiac output (16). It also causes peripheral vasoconstriction, which increases peripheral resistance and can lead to a sustained rise in blood pressure (16). In general, the increase in blood pressure is dose dependent (8), but doses under 50 mg do not always produce such an effect (14,17).

Chronic use of ephedrine for the management of asthma results in tachyphylaxis, making it an unreliable long-term therapeutic agent (16). Frequent doses become less effective as a result of the depletion of norepinephrine stores as well as the release of adenosine into synaptic junctions and increased cellular phosphodiesterase activity, both of which suppress catecholamine release (18). To potentiate the effects of ephedrine, methylxanthines (e.g., caffeine and theophylline), which interfere with the inhibitory effect of adenosine on both norepinephrine release and phosphodiesterase activity, are often combined with ephedra or ephedrine (19,20).

In the United States, ephedra-containing dietary supplements were widely promoted as weight loss aids because of their ephedrine content. The alkaloid has been postulated to do this by two mechanisms. First, by stimulating thermogenesis in laboratory animals (13,16,21) and humans (15,18), ephedrine increases energy expenditure. In rats, it has been shown to directly stimulate thermogenesis in brown adipose tissue via β -adrenergic receptors (16). However, studies in humans have provided evidence against the role of brown adipose tissue in ephedrine-induced thermogenesis (18). Although the site of action remains unclear, its thermogenic effect in humans has been widely confirmed and serves as the major rationale for its use as a weight loss aid. Second, the combination of ephedrine and caffeine acts as an appetite suppressant, reducing food intake. One study showed that about 75% of the effect of this combination on weight loss is the result of its anorectic properties, which may affect the satiety center in the hypothalamus (13,22). Evidence from animal studies and some human experiments shows that the combination reduces body fat but not lean body mass (13,23). However, because the human studies had few participants, larger studies would have to be carried out to confirm this finding.

The use of ephedrine as a nasal decongestant in over-the-counter preparations has been replaced for the most part by more selective β_2 -bronchodilators, but it is still included as a component of some pediatric prescription cold and cough medications and is found in a nonprescription medication for asthma (16). The ephedra constituent, pseudoephedrine is generally preferred as an oral decongestant because it is less potent and therefore less likely than ephedrine to cause central nervous system stimulation or hypertension (16).

Intravenous ephedrine is still widely used for the prevention and treatment of hypotension caused by spinal anesthesia, particularly during cesarean section (16). Other uses have included treatment of chronic urticaria, diabetic neuropathic edema, nocturnal enuresis, motion sickness, spastic or hypermotile bowel, and myasthenia gravis (24,25).

In addition to ephedrine alkaloids, some ephedra species include other nitrogen-containing secondary metabolites with known neuropharmacological activity (5). These include several cyclopropyl analogs of L-glutamate and methanoproline, and a cyclopropyl analog of L-proline, as well as common amino acids such as L-glutamate, L-glutamine, L-serine, and L-proline.

The stems of several ephedra species also contain kynurenates, derivatives of tryptophan catabolism that may help protect the plant from birds or rodents, but their physiological function is unknown (5). Kynurenates in ephedra stems exhibit antimicrobial activity against some gram-positive and gram-negative bacteria, although they are significantly less potent than the antibiotic ciprofloxacin.

Non-nitrogenous compounds found in some ephedra species include organic acids, phenolic compounds (flavonoids and tannins), and essential oils primarily composed of terpenoids (38.9%) (2,5). The tannin fractions have been shown to inhibit angiotensin converting enzyme activity, although to a much smaller degree than captopril.

Extracts of the roots contain the spermine-type alkaloids ephedradines A, B, C, and D, feruloylhistamine, and bisflavanols and cause hypotension when administered intravenously (2,26). The roots (*ma huang gen*) are not used in commercial dietary supplement products and are only a minor constituent of formulations used in traditional Chinese medicine.

PHARMACOKINETICS

Ephedrine is well absorbed after oral administration, is excreted largely unchanged in the urine, and has a serum half-life of 2 to 3 hours (14,27). When ingested in the form of *ma huang*, it has a t_{\max} (time of occurrence for peak drug concentration) of nearly four hours compared with only two hours for pure ephedrine (17).

Peak ephedrine blood levels are similar regardless of whether the alkaloid is taken as a herbal preparation or in the pure form. Ingestion of 400 mg of *ma huang* containing 20 mg ephedrine resulted in blood concentrations of 81 ng/mL, which is the same as the peak ephedrine levels observed after administering an equivalent amount of pure ephedrine (17).

PRECLINICAL STUDIES

Ephedra and its constituents have been studied in animals for a wide range of indications, including ulcer prevention, reduction of uremic toxins in renal failure, and immune modulation, as well as for their antimicrobial, antidiabetic, anti-inflammatory, antioxidant, and antitussive activities (2). Ephedrine has also been used in preclinical research to examine the efficacy and potential mechanisms of action of ephedra for weight loss (2,13).

CLINICAL TRIALS

A systematic review of the literature was conducted by RAND for published and unpublished sources of controlled clinical trials on ephedra and ephedrine used for weight loss and athletic performance in humans (6). Fifty-two controlled clinical trials of ephedrine or botanical ephedra used for weight loss or athletic performance enhancement in humans were included.

Efficacy for Weight Loss

Forty-four controlled trials were identified that assessed ephedra and ephedrine alkaloids used in combination with other compounds for weight loss, and 20 of these met inclusion criteria for the meta-analysis. Five pairs of treatment regimens were compared:

1. Ephedrine versus placebo (five studies): Ephedrine was associated with 1.3 lb/mo weight loss greater than placebo for up to four months of use.
2. Ephedrine plus caffeine versus placebo (12 studies): Ephedrine plus caffeine was associated with 2.2 lb/mo weight loss greater than placebo for up to four months of use.
3. Ephedrine plus caffeine versus ephedrine (three studies): Ephedrine plus caffeine was associated with 0.8 lb/mo weight loss greater than ephedrine alone.
4. Ephedrine plus herbs containing ephedra plus caffeine (three studies): Ephedra plus herbs containing caffeine was associated with 2.1 lb/mo weight loss greater than placebo for up to four months of use.
5. Ephedrine versus other active weight loss products (two studies): No conclusions could be drawn about ephedrine versus other active weight loss products because the sample size in these studies was too small.

Only one study compared an ephedra-containing product without caffeine but with other herbs and a placebo. This product was associated with a weight loss of 1.8 lb/mo, more than that associated with a placebo for up to three months of use.

None of the studies lasted longer than six months; hence, long-term weight loss and maintenance could not be assessed. The results indicate that the use of ephedrine, ephedrine plus caffeine, or dietary supplements containing ephedra plus herbs containing caffeine was associated with a statistically significant increase in weight loss for up to four months.

Efficacy for Athletic Performance Enhancement

There are no controlled clinical studies for athletic performance enhancement. RAND identified eight controlled trials of the effects of synthetic ephedrine for athletic performance enhancement, usually along with caffeine. The studies could not be pooled for meta-analysis because of the wide variety of interventions used. A few studies assessing the effect of ephedrine plus caffeine showed a modest improvement in very short-term athletic tasks such as weightlifting (1–2 hr after a single dose) and time to exhaustion for aerobic exercises. However, these trials were of very short duration and were done in small numbers of healthy young men, mostly military recruits. The results therefore cannot be generalized to the general public. Because all the studies were done in the same laboratory, the ability of other investigators to confirm the results has not been tested.

Published just before the FDA ban, a randomized trial of 15 healthy volunteers demonstrated that a single dose of a dietary supplement product containing ephedra and caffeine among other ingredients statistically significantly prolonged the QTc interval to longer than 30 milliseconds, a potentially dangerous effect (28).

Since the FDA's ban on the sale of dietary supplements containing ephedrine alkaloids, no clinical trials of significant size or duration have appeared in the scientific literature.

TOXICOLOGY

In Vitro Toxicity

The toxicity of eight water extracts of ephedra prepared from the entire plant using either ground or whole herb, boiled for 0.5 or 2 hours, and with either one or two extractions, was tested in a human hepatoblastoma cell line (HepG2) and a variety of animal cell lines (29). Of the cell lines tested, only a neuronal cell line (Neuro-2a)

showed significant sensitivity to the cytotoxic effects of the extracts. Grinding increased the toxicity of the resulting extracts. Normalizing the results for ephedrine content showed that the toxicity of the ephedra extracts could not be accounted for solely by ephedrine content, indicating the presence of other cytotoxic constituents. Kynurenates and cyclopropyl amino acids, both of which cause central nervous system toxicities and have been isolated from some species of ephedra, could be associated with the additional toxicity (5). However, neurotoxicity is eliminated during the boiling of extracts that are used in commercial products.

In studies performed by the National Toxicology Program, ephedrine was not mutagenic in four strains of *Salmonella typhimurium* and did not cause chromosomal aberrations in vitro in Chinese hamster ovary cells (30). Other in vitro researches of ephedrine or water or methanol extracts of ephedra have also not demonstrated any mutagenic effects (31,32).

In Vivo Toxicity

Several studies in mice have determined the oral LD₅₀ (median lethal dose) of water extracts of ephedra, which ranges from 4000 to 8000 mg/kg depending on the alkaloid content of the species used (2). On the basis of these measurements, the equivalent range of ephedrine was calculated to be 520 to 720 mg/kg.

The National Toxicology Program also evaluated the toxicity of ephedrine in B6C3F1 mice and F344 rats. During two-year studies, the animals were given diets containing 0, 125, or 250 ppm ephedrine per day. The mean body weight of the rats and mice receiving diets containing either dose of ephedrine was lower than those of controls, and survival was similar for the controls and exposed animals (30).

A teratogenicity study of ephedrine showed a frequency of 8% malformed chick embryo hearts with exposure to 0 or 0.5 μ mol ephedrine that increased to 26% for 5.0 μ mol (33).

A study in rats showed that the cardiotoxic effects of ephedra are significantly increased at doses at or above the ephedrine equivalent of 25 mg/kg, and that these effects are further increased with the addition of caffeine (34).

ADVERSE EVENTS

The safety of ephedra-containing dietary supplements has been a controversial subject, resulting in a high level of interest from regulators, manufacturers, and the public. MedWatch, the Adverse Reaction Monitoring System of the FDA, has recorded many reports of side effects concerning ephedra-containing products.

Ephedra-containing products were the subject of significant media coverage for quite a few years because of the deaths of several professional athletes who were allegedly taking these products (6). As a result of these safety concerns, ephedra was prohibited by the International Olympic Committee and the National Football League (6).

A review of the adverse effects reported in 50 controlled clinical trials of ephedra, ephedrine with or without caffeine, or botanicals containing caffeine concluded that

use of these substances was associated with 2 to 3 times the risk of nausea, vomiting, psychiatric symptoms, autonomic hyperactivity, and palpitations compared with placebo (35). No serious adverse events such as myocardial infarction, stroke, or death were reported in these studies, but the authors of the review noted that the small total number of patients in these experiments was not adequate to distinguish a serious adverse event rate of 1 in 1000 or higher.

To evaluate the incidence of serious side effects, several researchers reviewed ephedra-related adverse event reports in MedWatch as well as case reports in the published literature. The latter were evaluated in the RAND review because the total number of participants in the clinical trials was not sufficient to adequately assess the possibility of rare outcomes. Although such adverse event reports are not conclusive evidence of a cause-and-effect relationship, they can indicate the potential for such a relationship.

RAND searched the literature for published case reports and the MedWatch database for cases of serious adverse events that were idiopathic in etiology. If use of ephedra or ephedrine-containing products was well documented, then the possibility that ephedra or ephedrine caused the event was considered. Sentinel events were defined as adverse events associated with ingestion of an ephedra-containing product within 24 hours prior to the event and for which alternative explanations were excluded with reasonable certainty. Possible sentinel events were defined as adverse events that met the first two criteria for sentinel events but for which alternative explanations could not be excluded. RAND reviewed 71 cases reported in the published medical literature, 1820 case reports from the MedWatch database, and more than 18,000 consumer complaints reported to a manufacturer of ephedra-containing dietary supplements. The documentation for most reports was insufficient to support decisions about the relationship between the use of ephedra or ephedra-containing dietary supplements and the adverse event. Only 65 cases from the published literature, 241 from MedWatch, and 43 from a manufacturer of ephedra-containing dietary supplements had documentation sufficient for them to be included in the adverse event analysis. Among these, RAND identified 2 deaths, 3 myocardial infarctions, 9 cardiovascular accidents, 3 seizures, and 5 psychiatric events as sentinel events and 9 deaths, 6 myocardial infarctions, 10 cardiovascular accidents, 9 seizures, and 7 psychiatric events as possible sentinel events (35). About half of the sentinel and possible sentinel events occurred in individuals younger than 30 years.

Another study identified 140 MedWatch reports of adverse events concerning ephedra-containing products between June 1, 1997 and March 31, 1999 and concluded that 31% were definitely or probably related to use of these products and another 31% were possibly related (36). The events included death, stroke, hypertension, tachycardia, palpitations, and seizures.

A third study reviewed the MedWatch database for stroke, myocardial infarction, or sudden death associated with the use of ephedra-containing products from 1995 to 1997 (27). Of 926 cases of adverse event reports concerning the use of ephedra-containing products, 37 serious

cardiovascular events were identified as being temporally associated with the use of these products.

On the basis of this information, in April 2004, the FDA banned the sale of dietary supplements containing ephedrine alkaloids.

Subsequent to the FDA ban, other case reports of adverse events potentially associated with the use of dietary supplements containing ephedra have been published that include incidences of cardiomyopathy, stroke, coronary thrombosis, and serious psychiatric events (37–42).

CONTRAINDICATIONS

Because of the potentially dangerous effects of ephedrine on the heart and central nervous system, individuals with a history of cardiovascular disease; hypertension; hyperthyroidism; seizures; depression or other mental, emotional, or behavioral conditions; glaucoma; or difficulty in urinating because of benign prostatic hypertrophy should avoid taking ephedra-containing products (43).

Ephedrine is often used for intraoperative hypotension and bradycardia, raising concerns about preoperative use of ephedra-containing products. Such application puts people anesthetized with halothane at risk because halothane sensitizes the myocardium to ventricular arrhythmias (14).

The potential for serious side effects rises as serving size and frequency of use is increased (44). These risks may also be enhanced when ephedra-containing products are used with other sources of stimulants such as caffeinated beverages, over-the-counter drugs, and other dietary supplements containing stimulants.

DRUG INTERACTIONS

Ephedra-containing products should not be taken with, or for two weeks, after monoamine oxidase inhibitors or with drugs for Parkinson disease, obesity, or weight control; methyl dopa; or any product containing ephedrine, pseudoephedrine, or phenylpropanolamine (43).

FUTURE RESEARCH

To assess the safety of ephedra, a rigorous case-control study of ischemic vascular, cardiovascular, and heat stroke events should be given a high priority.

Basic research is needed on pharmacokinetic drug interaction assessments, including identification of interactions with agents such as anabolic steroids or sympathomimetics, and on physiological responses under conditions such as exercise and thermal stress.

Clinical trials will be necessary to assess the risk-benefit ratio of ephedra for weight loss among overweight and obese individuals. A phase II study could be used to evaluate adverse events, weight loss, physiological responses, and optimal dosing. A randomized clinical trial of adequate sample size could then be used to characterize side effects and evaluate efficacy with regard to moderate

or long-term weight loss and maintenance and relevant health outcomes.

The research portfolio described above would be time consuming and expensive but would answer the questions of ephedra safety and efficacy definitively. However, it is likely that as a result of the FDA's ban on dietary supplements containing ephedrine alkaloids this research will not be done.

Evening Primrose

Fereidoon Shahidi and Homan Miraliakbari

INTRODUCTION

Intake of dietary fat, particularly essential fatty acids, is known to influence human health and disease status. Evening primrose oil (EPO), a source of γ -linolenic acid, has received much attention for its possible therapeutic effects on inflammatory and cardiovascular diseases, diabetes, and cancer, among others. The beneficial health effects attributed to the oil are thought to be mediated by the desaturated metabolite of γ -linolenic acid, namely dihomo- γ -linolenic acid, which is metabolized in the body to produce anti-inflammatory eicosanoids that may reduce the incidence or severity of human disease status and to promote health. EPO is also a source of antioxidative tocopherols. This entry attempts to summarize the effects of EPO in health promotion and disease risk reduction.

BACKGROUND

Evening primrose (*Oenothera biennis*) is a biennial herb with erect stems reaching 3 ft in height and has fragrant, yellow flowers that bloom at nightfall (evenings). The plant is native to North America but has been naturalized in Europe and parts of the Southern Hemisphere. Following pollination (usually performed by moths), short and cylindrical capsules containing many small seeds are formed (1). The oil extract of evening primrose seeds (evening primrose oil or EPO) is a rich source of the essential polyunsaturated omega-6 (n -6) fatty acid, linoleic acid (65–80% of total fatty acids), and its desaturated metabolite γ -linolenic acid (8–14% of total fatty acids) (2). EPO is also a good source of α -tocopherol (3). Several reports show that EPO is beneficial in the promotion of human health and in the treatment of several diseases, including heart diseases, cancer, inflammatory diseases, diabetes, and diseases related to women's health (4). However, the U.S. Food and Drug Administration has not approved the use of EPO for any of the health claims attributed to its use (5). Among others, the oil is available as a dietary supplement in North America and Europe. Several moderately to highly refined dietary oil supplements containing EPO have been developed and marketed for specific uses including Efamast[®] for benign breast pain and Epogam[®] for atopic eczema, although no health agencies support these claims.

Essential Fatty Acids

Humans are unable to synthesize polyunsaturated fatty acids (PUFAs), but are able to elongate and desaturate

their 18-carbon (C_{18}) precursors obtained through the diet (6). In humans, two essential PUFA families, namely, the omega-6 (n -6) and the omega-3 (n -3) families, are recognized with linoleic acid (18:2, n -6) and α -linolenic acid (18:3, n -3), serving as their parent compounds, respectively. The designation n -6 and n -3 indicates whether the sixth or the third carbon from the methyl terminus is unsaturated. EPO is a rich source of the n -6 fatty acid, γ -linolenic acid (18:3, n -6), which can be elongated in vivo to produce dihomo- γ -linolenic acid (20:3, n -6) and then desaturated to produce arachidonic acid (20:4, n -6). Several putative health benefits of EPO have been attributed to γ -linolenic acid and its metabolites (4).

Metabolic Functions of Omega-6 Fatty Acids

In humans, linoleic acid (18:2, n -6) is the essential fatty acid required in the highest amount, which is estimated to be approximately 1% to 2% of total caloric intake in adults (7). Dietary linoleic acid can be elongated and desaturated in the body to produce other long-chain n -6 fatty acids. If dietary linoleic acid intake is deficient, γ -linolenic acid (18:3, n -6), dihomo- γ -linolenic acid (20:3, n -6), arachidonic acid (20:4, n -6), and docosapentaenoic acid (22:5, n -6) become essential. Hence, these fatty acids are referred to as conditionally essential (Fig. 1) (8). Both n -6 and n -3 fatty acids are chain elongated through the same biosynthetic pathways. Thus, elongation and desaturation of long-chain n -3 and n -6 PUFAs are proportional to the dietary intake of their C_{18} precursors (9). The efficiency of fatty acid elongation pathways in humans is estimated to be 5% to 7% under optimal conditions when adequate dietary C_{18} essential fatty acids are present (9).

The C_{18} n -6 and n -3 fatty acids are essential partly because they are the precursors of C_{20} and C_{22} lipid-based cytokines or eicosanoids [prostaglandins (PG), thromboxanes (TX), and leukotrienes (LT)]. These lipid mediators play crucial roles in vascular physiology and inflammatory responses, among others (10). The long-chain n -6 and n -3 fatty acids have also been beneficial in many diseases, for example, cancer (11), cardiovascular diseases, including stroke (12). Therapeutic health effects of EPO have often been attributed to its high content of γ -linolenic acid, which is elongated in vivo to dihomo- γ -linolenic acid (13), which can then be metabolized via the cyclo-oxygenase or lipoxygenase enzyme families to yield series-1 PG and TX or series-3 LT, respectively. The cyclo-oxygenase and lipoxygenase products of dihomo- γ -linolenic acid and hence EPO have been shown to exert anti-inflammatory (14), anti-proliferative (15), and anticarcinogenic (16) effects. However, the desaturase product of

Figure 1 Essential and conditionally essential fatty acids of the omega-6 (*n*-6) family.

dihomo- γ -linolenic acid, arachidonic acid (20:4, *n*-6), is metabolized to produce proinflammatory PG and LT that may negate the anti-inflammatory potential of dihomo- γ -linolenic acid in vivo (17).

The long-chain *n*-6 and *n*-3 fatty acids play important roles in maintaining the fluidity or optimal state of cell membranes and are key components in the membranes of highly specialized cells such as neurons, erythrocytes, cardiomyocytes, retinocytes, germ cells, and immune cells (18). Linoleic acid and elongation products thereof have a role in maintaining epidermal integrity. They are essential for the development and maintenance of the skin's water-impermeable barrier, the stratum corneum (19). The elongation products of *n*-6 and *n*-3 fatty acids are also required for proper growth and development of the brain and retina during gestation and infant life (20), and for normal brain function and vision in adults (21). More recently, these products have been shown to affect gene expression, leading to pronounced changes in metabolism, cellular differentiation, and growth (22).

EPO AND INFLAMMATORY DISEASES

Chronic inflammation associated with diseases such as inflammatory bowel disease, psoriasis, arteriosclerosis, and rheumatoid arthritis may be caused or attenuated by alterations of normal eicosanoid pathways resulting in overproduction of inflammatory cytokines. Many anti-inflammatory drugs act as inhibitors of proinflammatory cytokine production. For example, nonsteroidal anti-inflammatory drugs (NSAIDs) (acetylsalicylic acid or aspirin) irreversibly inactivate cyclo-oxygenase activity, thereby inhibiting proinflammatory PG and TX biosynthesis. EPO may be of use in the treatment and/or management of some inflammatory diseases because it has been shown to reduce proinflammatory eicosanoid biosyn-

thesis, while concomitantly increasing anti-inflammatory biosynthesis both in vitro and in vivo (23). Currently, there is much research investigating their therapeutic potential for inflammatory diseases.

Several research groups have performed feeding studies with EPO to unravel its effects on proinflammatory cytokine production in cell-based in vitro model systems (24). In one recent study (25), 3-week-old male Wistar rats were fed diets supplemented with oils including EPO for eight weeks. Experimental diets contained 15% EPO, sardine oil, or virgin olive oil by weight, while control diets contained 2% corn oil. After the eight-week feeding period, lymphocytes and other blood cells were obtained from the peritoneal region of animals from all four groups and were purified to yield a suspension containing approximately 85% polymorphonuclear leukocytes and 15% mononuclear lymphocytes. The leukocyte suspensions were stimulated with the calcium ionophore (A23187) to induce the production of cyclo-oxygenase-derived eicosanoids, which were quantified by radioimmunoassay. In these studies, leukocytes from EPO-fed animals had reduced the production of proinflammatory prostaglandin E₂ (PGE₂) and thromboxane B₂ (TXB₂) compared to those from control animals. However, the difference reached significance for PGE₂ only (25). Larger and more important differences were observed for leukocytes from the fish oil-fed animals but not for those with virgin olive oil. These results show that EPO may be an effective anti-inflammatory agent because its long-term dietary presence reduces lymphocyte reactivity, possibly because of its γ -linolenic acid constituent (25).

EPO and Atopic Dermatitis

Atopic dermatitis, also known as atopic eczema, is an immune-mediated inflammatory skin disorder characterized by redness, itching, and oozing vesicular lesions that become scaly, crusted, or hardened (26). Corticosteroid

and antipruritic treatments are common for addressing atopic dermatitis, but concerns regarding the side effects of these drugs have prompted search for alternative natural and less toxic treatments (27). The effects of EPO supplementation on atopic dermatitis have received much attention because the fatty acid composition of the oil may interfere with the production of proinflammatory cytokines, which could potentially reduce the symptoms of this disease (28). Furthermore, low Δ -6-desaturase activity leading to γ -linolenic acid deficiency has previously been reported as a contributing factor to atopic dermatitis (29), making EPO (with its high γ -linolenic acid content) the subject of much interest in eczema therapy. Morse et al. (30) performed a meta-analysis on nine placebo-controlled studies investigating the efficacy of EPO supplementation in the treatment of atopic dermatitis; the individual studies were performed in eight different centers (30). This analysis included two of the earliest large-scale studies on EPO and eczema as well as seven small ones (14–47 participants). In these studies, patients and doctors assessed the severity of eczema in experimental and placebo groups by scoring measures for skin symptoms including itchiness, dryness, and scaliness. Subjects in the experimental groups were provided with Epogam EPO capsules containing 10% γ -linolenic acid. Results from all studies were pooled together to give a global clinical score for each assessment point. This early meta-analysis showed that the clinical scores for patients receiving Epogam supplements were significantly better than those for placebo groups, particularly for the symptom of itch ($P < 0.0001$). Furthermore, there was a positive correlation between plasma dihomo- γ -linolenic acid levels and clinical score improvement (30). However, the results of this meta-analysis have been questioned by experts for two main reasons: First, it did not consider the relatively large study by Bamford, Gibson, and Renier (31), which included 123 participants and did not demonstrate any therapeutic effect of EPO on eczema. Second, this meta-analysis as well as seven of the studies referenced by it was sponsored by Scotia Pharmaceuticals, the manufacturer of Epogam. Some recent studies have failed to reflect the efficacy of EPO as treatment for atopic eczema, as exhibited in the placebo-controlled trial conducted by Hederos and Berg (32) that included 60 eczemic children supplemented with Epogam for 16 weeks as well as in the larger placebo-based trial by Berth-Jones and Graham Brown (33) that included 123 patients. It has been postulated that EPO treatment may modify immunological parameters associated with atopic dermatitis such as plasma interferon- γ (INF- γ) and immunoglobulin-E (IgE) levels (34,35). Recently, Yoon, Leg and Lee (35) investigated this possibility in 14 children with atopic dermatitis. A group of six children without the disorder were used as normal controls. EPO was administered to participants with atopic dermatitis until their symptom scores remained below one for two weeks. EPO treatments lasted 75 ± 58 days; all participants receiving EPO exhibited clinical improvements and $>42\%$ of this group were completely cleared of symptoms of atopic dermatitis. Before EPO treatments, the mean plasma INF- γ levels in the experimental group were significantly lower than that of the control group ($P < 0.01$). But after treatments, INF- γ levels in the experimental group increased

to a level equal to that of the control group ($P < 0.01$) (35). Plasma IgE levels of the experimental group were significantly greater than that of the control group both before and after the treatment. The results of this study imply that EPO is therapeutic in children with atopic dermatitis, and the observed clinical improvements are likely due to the normalization of INF- γ levels and perhaps other immunological parameters (35).

Thus, no consensus exists among the results of different studies on the effects of EPO supplementation for atopic dermatitis. The heterogeneous nature of the patients, who can exhibit slight to very serious symptoms, may explain the observed inconsistencies (36). Recent reviews show that the current body of literature is too inconsistent, making it impossible to conclusively link EPO supplementation to improvements in eczema symptoms (37,38). Larger scale, placebo-controlled studies are needed to provide firm evidence about the postulated beneficial effects of EPO on atopic dermatitis symptoms.

EPO and Rheumatoid Arthritis

Arthritis is a degenerative chronic disease that can affect any of the body's joints. The term arthritis refers to the inflammation of a joint, but not all arthritic diseases involve inflammation. One very common type of the disease is rheumatoid arthritis, which is a chronic inflammatory disease involving the body's immune system. According to Health Canada, four million Canadians suffer from arthritis. Rheumatoid arthritis is an autoimmune condition that occurs in younger adults and sometimes in children. It is due to the release of inflammatory cytokines into the fluid space between the bones of a joint (synovium), which causes chronic inflammation of the cartilage covering the ends of the bones. The most common symptoms are pain, stiffness, and, if left untreated, bone deformity (15). The Raynaud phenomenon and Sjögren syndrome are two inflammatory diseases commonly seen in rheumatoid arthritis patients (39). Raynaud phenomenon is an immunological syndrome characterized by vascular spasms and enhanced blood cell aggregation that leads to ischemia of the fingers, toes, ears, and nose and causes severe pain and pallor in the affected extremities (40). Sjögren syndrome is an immunological disease affecting predominantly women in their 30s and leads to the destruction of exocrine glands. The main symptoms include persistent cough and dry eyes and mouth (41). Ingestion of EPO enhances dihomo- γ -linoleic acid levels (42) and may promote the production of anti-inflammatory series-1 PG or reduce proinflammatory series-2 PG production, which may be of benefit to rheumatoid arthritis patients. To investigate this possibility, research has been performed on the effects of EPO on rheumatologic conditions.

Two early studies investigating the effect of EPO supplementation on rheumatoid arthritis symptoms were conducted by Brown et al. (43) and Hansen et al. (44). Both studies involved only 20 or less participants who were supplemented with low daily doses of EPO (< 1 g) for three to four months. The tests showed no significant improvements, although a trend toward amelioration was observed in rheumatoid arthritis sufferers in the study by

Hansen et al. (44). Jantti et al. (45) studied the effects of EPO or olive oil administration (approximately 1.4 g/day) for 12 weeks on sufferers. This research was unique because participants were required to abstain from NSAID use for the duration of the study, which could potentially negate the possible therapeutic effects of EPO if they are mediated by the anti-inflammatory PG and TX products of dihomo- γ -linolenic acid (45). Compared to baseline, neither the olive oil nor EPO group exhibited any clinical improvements in rheumatoid arthritis symptoms (45). Although these early studies did not provide evidence of EPO's therapeutic effects, it is possible that the supplementation regimes were insufficient and that higher doses of the oil given over a longer period may improve rheumatoid arthritis symptoms. More recently, Brzeski, Madhok, and Capel (46) examined the effects of supplementation of 6 g of EPO or olive oil per day for six months on symptom management in 40 rheumatoid arthritis sufferers. While olive oil supplementation was supposed to act as a placebo, a significant improvement was, however, noted at the end of the six-month evaluation period compared to baseline, similar to that observed for participants in the EPO group. Thus, both olive oil and EPO supplementations were equally effective in improving the clinical scores of rheumatoid arthritis sufferers, and selection of an appropriate placebo must be carefully exercised in such studies so that the possible therapeutic effects of EPO are not masked. Belch et al. (47) studied the effects of EPO and EPO plus fish oil (approximately 6 g/day) on rheumatoid arthritis symptoms in 49 participants over a 12-month supplementation period. In this study, 16 patients were given EPO, 15 EPO plus fish oil, and 18 liquid paraffin as placebo (47). Measures of disease activity and NSAID use were used to assess the effectiveness of the treatments. After the supplementation period, NSAID use was lower in both the EPO and EPO plus fish oil groups. However, no clinical improvements were observed in either treatment group implying that EPO did not serve as a disease-modifying agent for rheumatoid arthritis (47). The results of a similar, but larger, study including 402 rheumatoid arthritis patients were reported by Darlington and Stone (48). This was a multicenter, double-blind, and placebo-controlled trial. Participants were randomized into one of two groups receiving between 2 and 3 g/day of EPO (experimental group) or sunflower oil (placebo); the duration of the treatment period may not have been consistent among the centers. The results of this study did not reveal any therapeutic effects of EPO in sufferers of rheumatoid arthritis (48).

The current body of literature regarding EPO supplementation and rheumatoid arthritis does not provide any clear understanding regarding its therapeutic effects; few studies, however, show a clear improvement in symptoms, but many refute its therapeutic potential, because of the use of faulty designs. Some of these studies have used inappropriate placebos, others have recruited participants exhibiting a wide range of disease symptoms, and many have used treatment doses that were too small to promote clinical improvements in sufferers of rheumatoid arthritis. Larger scale, placebo-based trials are needed to conclusively evaluate the effects of EPO on rheumatoid arthritis.

EVENING PRIMROSE AND CARDIOVASCULAR DISEASE

Cardiovascular disease is the common term for all diseases that affect the heart and circulatory system, including ischemic, nonischemic, hypertensive, and valvular heart disease. It is the leading cause of death in the Western societies (49) and has been linked to the high fat intake, particularly saturated fat, common in the Western diet (50). Besides high saturated and trans fat intake, other risk factors include diabetes mellitus, smoking, stress, physical inactivity, high sodium intake, and genetic predisposition. The hallmark of cardiovascular disease is cardiac dysfunction, which in most cases is caused by hypertension due to the narrowing of large arteries with atheromatous plaques or the total occlusion of coronary arteries (thrombus) caused by atheromatous blockages leading to myocardial tissue necrosis. Both conditions reduce the heart's ability to pump blood and can result in either chronic or sudden heart failure.

Several reports indicate that ingestion of dietary PUFA reduces the likelihood of cardiovascular disease. Much attention has been paid to the antithrombotic and antiatherogenic effects of *n*-3 fatty acids of fish oils, while oils rich in *n*-6 fatty acids have evoked relatively less interest (51). Arachidonic acid is the major metabolite produced from dietary linoleic acid, and eicosanoids produced from arachidonic acid are known as being proaggregatory. Thus, *n*-6 fatty acids have been speculated to promote thrombosis and atherogenesis (52). However, not all dietary *n*-6 fatty acids become elongated and desaturated into arachidonic acid. For example, dietary γ -linolenic acid is rapidly converted into dihomo- γ -linolenic, which is the precursor of the antiaggregatory vasodilator, PGE₁ (52). EPO is a source of antioxidative compounds such as α -tocopherol (53), which may protect highly oxidizable biomacromolecules such as low-density lipoproteins (LDL) from oxidation *in vivo*, which is known to precede some aspects of cardiovascular disease, most notably blood vessel damage (54). The fact that EPO is a source of γ -linolenic acid and antioxidative compounds has led researchers to investigate its possible cardioprotective effects. Most of these studies have been conducted using animal models of cardiovascular disease.

Singer et al. (55,56) using spontaneously hypertensive rats, revealed that dietary EPO intake alters blood lipid profiles and systolic pressures, thereby improving cardiovascular risk factors (55,56). The dietary proportions and types of fats consumed can alter platelet–blood vessel interactions. Long-chain *n*-3 fatty acids and dihomo- γ -linolenic acid may exert antithrombotic activity because their eicosanoid metabolites reduce platelet aggregability, a known cardiovascular risk factor (57). De la Cruz et al. (58) investigated the ability of EPO to reduce blood platelet aggregation in response to inducers (adenosine diphosphate or collagen) using a total of 40 male white New Zealand rabbits fed normal and atherogenic diets. These researchers also measured platelet thromboxane synthesis and malondialdehyde (MDA) production to assess blood platelet reactivity. Two control groups were used in this study: one group received a low-fat diet (2.1%, w/w) with normal lipid composition (normal diet group), while the

other was fed a high-fat diet (12.2%, w/w) containing primarily saturated fatty acids (atherogenic diet group). The diets of experimental animals were supplemented with EPO to get a total fat content between 19.8% and 20.3%. These feeding trials lasted six weeks; on the last day, the animals were anesthetized and blood samples were obtained for subsequent analysis. Compared to the normal control diet, the atherogenic control diet resulted in hyperlipidemia (hypercholesterolemia and hypertriglyceridemia) with a concomitant decrease in high-density lipoprotein (HDL) levels. Platelet aggregation and platelet production of thromboxane B₂ (TXB₂) and MDA were several times greater in the atherogenic diet group compared to controls. Supplementation of EPO in normal diets did not alter blood lipid and platelet parameters compared to normal controls. However, EPO significantly reduced total blood cholesterol and triacylglycerols, while increasing HDL levels in animals fed atherogenic diets, and reducing blood lipid aggregation level to that of normal control values ($P < 0.05$ – $P < 0.01$). Treatment also reduced TXB₂ and MDA production by platelets from animals fed atherogenic diets, although these values were still significantly higher than those of the control animals fed on a normal control diet ($P < 0.05$ – $P < 0.01$). Diets rich in saturates promoted the onset of cardiovascular risk factors such as platelet reactivity and aggregation, and EPO treatment normalized these parameters substantially in male New Zealand white rabbits (58). More recently, De la Cruz et al. (59) assessed the antioxidant potential of EPO in 40 male white New Zealand rabbits that were fed atherogenic diets (50% fat, w/w) or normolipidic diets (20% fat, w/w) containing 15% EPO (w/w); controls were fed either atherogenic or normolipidic diets without EPO enrichment. The duration of the feeding period was six weeks, after which all animals were sacrificed, and samples of liver, brain, heart, aorta, and blood platelets from each animal were collected to test MDA and glutathione levels. The results of this study showed that in normolipidic diets, EPO treatment did not alter MDA production or glutathione levels. However, atherogenic diets promoted MDA production (both induced and noninduced TBARS) and glutathione oxidation in all tissues and platelets. Meanwhile, tissues of animals receiving atherogenic diets plus EPO exhibited a lesser induction of MDA production and glutathione oxidation ($P < 0.05$ – $P < 0.01$). Thus, EPO supplementation may reduce the production of lipid oxidation products in tissues, which are implicated in the onset of atherosclerosis (59). The cardioprotective effects of EPO may be due to the presence of antioxidative components. Charnock (60) recently evaluated the effects of dietary EPO, sunflower oil, borage oil, and saturated fat against ventricular fibrillation in male Hooded-Wistar rats fed normal chow diets supplemented with 6% EPO (w/w) for 32 weeks. At the end of the feeding period, the animals were anesthetized and ventilated, followed by surgical ligation (occlusion) of the left descending coronary artery to induce ventricular fibrillation and cardiac arrhythmia. In this study, incidence and duration of ventricular fibrillation were lowest in the EPO group. Interestingly, EPO exerted a protective effect against ventricular fibrillation, which exceeded that of borage oil (containing three times more γ -linolenic acid than EPO). This implies that γ -linolenic acid may not

be the therapeutic component of EPO; some other compounds present in EPO may exert cardioprotective effects in this animal model (60).

Very few investigations on the cardioprotective effects of EPO have been carried out in humans. Abraham et al. (61) examined changes in the fatty acid composition of adipose tissue, serum triacylglycerol and cholesterol ester levels, and lipoprotein profiles in men with low dihomo- γ -linolenic acid levels supplemented with safflower oil or EPO for four months. Participants in this study were split into four groups (6–9 men per group) receiving 10, 20, or 30 mL/day of EPO or 20 mL/day of safflower oil. Adipose and blood samples were obtained from participants before and after the treatment period. Treatment with EPO at levels ≥ 20 mL/day increased adipose dihomo- γ -linolenic acid levels ($P < 0.01$); safflower oil did not increase adipose dihomo- γ -linolenic acid content. Within individual participants, similar trends were observed between adipose fatty acid compositions and serum triacylglycerol and cholesterol ester fatty acid compositions. Safflower oil and EPO treatments did not significantly lower LDL or raise HDL levels, implying that EPO may not exert strong antiatherogenic effects in humans, contrary to the findings from the animal models (61). However, Abraham et al. (61) used a highly select group of men most likely possessing low Δ -6-desaturase activity, which may have affected the outcome of this study. More recently, Khan et al. (62) performed a double-blind placebo-based study to examine the effects of an eight-month treatment with food oils on vascular tone and endothelial function in 173 healthy volunteers (118 males and 55 females). The placebo oil used was 25:75 (w/w) mixture of soybean oil and coconut oil, administered at 10 g/day to the placebo group. Participants in the EPO group received 5 g EPO plus 5 g placebo oil per day. The results for the EPO group showed that it did not alter the vasodilator responses to acetylcholine (general endothelial function) or sodium nitroprusside (endothelium-independent vasodilation) in healthy volunteers (62).

The majority of results from human and animal studies exhibit different findings with respect to the cardioprotective effects of EPO, because certain invasive tests cannot be performed on humans. In animal models, specific cardiovascular conditions can be induced, thereby allowing researchers to more accurately measure specific responses to EPO. More research involving human subjects and possibly trials involving recovering cardiovascular disease patients already taking medication need to be done in order to assess whether EPO exerts any cardioprotective effects in medicated patients.

EPO AND CANCER

Cancer is a general term for more than 100 diseases that are characterized by uncontrolled and abnormal growth of cells (neoplasia) derived from normal tissues. Cancerous cells may develop into tumors that could produce toxins or spread locally or through the bloodstream and lymphatic system to other parts of the body (metastasis). The initial steps that lead to the transformation of normal cells into cancerous cells are not well understood.

But many lines of evidence implicate the involvement of mutated genes in cells progressing toward cancer. Cancer cells are incapable of apoptosis, a property that makes them potentially "immortal" (63). Two recognized treatments for cancer are chemotherapy, which is the administration of drugs (alkylating agents, e.g., vinblastine and chlorambucil) and radiation therapy in which cancerous tumors are subjected to ionizing radiation. Both treatments cause irreparable damage to the DNA of cancer cells, thereby promoting cell apoptosis. Currently, much research is being conducted to identify new cancer therapies with less adverse side effects and greater specificity toward cancer cells. Experimental and epidemiological studies have demonstrated that the composition of dietary fat affects the incidence and progression of some cancers (64).

Several cancerous cell lines have been developed from animal and human malignant tumors. They serve as excellent *in vitro* models for cancer studies because the biochemical processes that occur within these cells are remarkably similar to those within their parent tumors. Early reports using cancerous cell lines have shown that γ -linolenic acid and metabolites of this compound suppress cell proliferation (65). The fact that EPO is a dietary source of γ -linolenic acid has prompted several research groups to investigate its anticancer potential. Gardiner and Duncan (66) examined the effects of EPO and safflower oil on the growth of precultured BL6 melanoma tumors implanted in mice. After implantation, the mice were fed diets containing 6% EPO or safflower oil for four weeks after which tumor growth and Δ -6-desaturase activity were measured in each animal. Results showed that EPO promoted *in vivo* tumor growth to a greater extent than safflower oil and that the Δ -6-desaturase activities of the *in vivo* BL6 tumors were lower than that of *in vitro* BL6 tumors. These results collectively imply that BL6 tumor growth *in vivo* is enhanced in the presence of dietary γ -linolenic acid, which may ameliorate the antigrowth effects of low Δ -6-desaturase activity because γ -linolenic acid is a product of this enzyme's activity (66). Ramesh and Das (67) examined the effects of topical EPO or fish oil application on skin carcinogenesis in male Swiss albino mice. This study employed a multistage skin carcinogenesis model involving two clearly defined steps: initiation and promotion using noxious chemicals topically applied on the skin of mice. Treatments of 10 mg EPO or fish oil were used twice daily for 14 weeks, after which papilloma (benign skin tumors) counts and histopathological assessments of excised skin samples were performed. Both fish oil and EPO significantly reduced papilloma formation compared to the control animals receiving no topical EPO or fish oil treatment ($P < 0.05$). However, neither EPO nor fish oil could influence skin cell proliferation in this model. These results imply that EPO may interfere with the development of papillomas but cannot influence the metastatic properties of skin tumors in this model (67). Booyens et al. (65) studied liver cancer cell proliferation in six patients taking EPO supplements and reported a decrease in tumor sizes in three patients as well as considerable reductions in plasma levels of cancer markers (65). More recently, Kollias et al. (68) studied the effects of EPO (4 g/day) on breast fibroadenoma (benign solid

growth) in 20 female subjects. The treatment period lasted six months, after which clinical and ultrasound measurements of previously diagnosed fibroadenomas were compared. Results of these measurements showed that EPO treatment did not alter fibroadenoma size compared to matched controls (68).

Data from animal models imply that EPO may exert anticarcinogenic effects when consumed as a dietary component, and some human studies support these findings. However, the subset of studies involving human subjects has been small scale and is quite prone to errors due to interpatient variability. Larger scale human studies with subject populations that exhibit similar disease symptoms and severity are needed to provide strong support for the anticarcinogenic potential of EPO.

EPO AND WOMEN'S HEALTH

Several adverse health effects have consistently been observed in menopausal and postmenopausal women. Menopausal hot flashes, postmenopausal osteoporosis, and chronic breast mastalgia (chronic breast pain) are examples of adverse health states affecting women (69). The etiologies of these conditions are not well understood, but one common factor has been associated with their declining estrogen level (70). It has been speculated that alterations in hypothalamic activity may underline the clinical aspects of adverse menopausal conditions; however, this view is not accepted widely (71). For most women, estrogen replacement therapy is an effective treatment for adverse menopausal conditions. But several concerns regarding the long-term safety of estrogen replacement therapy have prompted the search for natural, nonhormonal substitutes, and EPO in this regard has received some positive attention (2).

Chenoy et al. (72) performed a randomized, double-blind, placebo-based trial to evaluate the effect of oral EPO consumption or paraffin supplementation (4 g/day for 6 months) in the treatment of hot flashes among 56 menopausal women. Results were based on reports given in diaries of all 56 participants, which showed no significant difference between EPO and placebo treatments despite numerous claims of its efficacy (72). Menopause is known to precede bone mineral density loss leading to osteoporosis that significantly weakens bones making them prone to fractures after light traumas. Adequate premenopausal calcium and vitamin D intakes are negative risk factors for osteoporosis, while smoking and back-to-back pregnancies are promotional risk factors. Bassey et al. (73) recently performed a randomized placebo-controlled trial to investigate changes in bone density markers in response to Efascal[®], an EPO plus eicosapentaenoic acid (EPA), and calcium supplement. This study included 43 pre- and postmenopausal women supplemented with either 4 g Efascal, 1 g calcium per day, or placebo. Final assessments were made after 12 months. Completed food frequency questionnaires were used to assess background calcium intake. The results of this study showed that Efascal treatments did not significantly alter bone mineral density or any other osteoporosis markers, which may indicate the lack of therapeutic efficacy of Efascal in

osteoporosis treatment or the already optimal nutritional state of participants in this study (73). Breast mastalgia is the most commonly diagnosed breast problem and can lead to severe pain that interferes with daily life. Effective medications are available, but the high frequency of side effect occurrence with these drugs has stemmed interest in alternative remedies for breast mastalgia (2). Recently, Blommers et al. (74) investigated the effects of fish oil and EPO on breast mastalgia in 120 premenopausal women. The participants were divided into four groups receiving either 3 g EPO plus 3 g fish oil per day, 3 g EPO plus 3 g corn oil per day, 3 g fish oil plus 3 g corn oil per day, or 6 g corn oil per day (the control group). The treatments were given for six months and symptom questionnaires were sent to participants three and six months into the trial and were compiled for subsequent symptom analysis. The results of this study showed no significant differences between the three experimental groups and the control group with respect to the number of days with active mastalgia, indicating that EPO supplementation may not be an effective treatment for breast mastalgia (74).

Premenstrual syndrome affects millions of premenopausal women and exerts a wide variety of symptoms including abdominal pain, breast tenderness, headache, depression, fatigue, and mood swings that usually subside within 72 hours after the onset of menstrual flow (75). The syndrome occurs more frequently in women with atopic allergies (76) and in those with a high saturated fat intake (77), which implicates abnormal fatty acid metabolism or dietary PUFA deficiency as promotional factors for premenstrual syndrome. Some reports have indicated that EPO may be effective in the management of premenstrual syndrome symptoms. However, few placebo-controlled trials have been conducted to investigate this possibility. Khoo, Munro, and Battistutta (78) examined the therapeutic effectiveness of EPO (Efamol®) in the relief of symptoms of premenstrual syndrome. This was a prospective, randomized, double-blind, placebo-controlled trial involving 38 women supplemented with 4 g/day of EPO or placebo for six months (six menstrual cycles). No significant differences in premenstrual syndrome symptoms were observed between the EPO and placebo groups throughout this study. Yet both groups did exhibit improvements in overall symptoms (psychological, fluid retention, and breast pain) implying that the improvement observed in the EPO group was due to the placebo effect (78). Budeiri, Li-Wan-Po, and Dornan (79) analyzed the results of seven placebo-controlled trials that investigated the effects of EPO on premenstrual syndrome symptoms (meta-analysis). The differences that existed between these studies made a rigorous meta-analysis impossible. EPO was shown to exert moderate beneficial effects compared to placebo for breast pain associated with premenstrual syndrome. Yet, it displayed no overall evidence of effectiveness in the management of premenstrual syndrome (79).

A link between pregnancy complications and low maternal PUFA status has been established. Marine diets rich in *n*-3 PUFA are known to reduce the incidence of gestation-induced hypertension (80), a condition characterized by increased platelet aggregation and vasoconstriction leading to thrombosis in nonhypertensive

women. If in addition to hypertension high urinary protein levels develop (proteinuria), the condition is called pre-eclampsia. Zielinski et al. (81) studied the effects of EPO against hypertension development in pregnant rabbits. In this study, pregnant and nonpregnant rabbits were supplemented with 50 mg/kg per day EPO for 10 days. Pregnant and nonpregnant rabbits on regular diets were used as controls. After the supplementation period, angiotensin II, a blood clotting factor, was administered to animals to induce hypertension, and the pressor response (increase in blood pressure) was measured. Results showed that EPO-supplemented pregnant rabbits exhibited a significantly lower systolic and diastolic response to angiotensin II compared to the control pregnant rabbits. No significant difference in the pressor response to angiotensin II existed between nonpregnant rabbits of both groups. These results may be attributable to the high levels of γ -linolenic acid that may have enhanced PGE₁ (antiaggregatory) synthesis. Coadministration of PGE₁ with angiotensin II reduces vascular responsiveness to angiotensin II (81). Moodley and Norman (82) performed a randomized placebo-based trial to study the effects of 4 g/day EPO administration in 47 women with established pre-eclampsia, showing that no difference in pre-eclampsia symptoms (blood pressure, and blood aggregability) existed between the two groups (82). One of the largest clinical trials investigating the effect of EPO treatment on women with pre-eclampsia was performed by D'Almeida et al. (83). A total of 150 women in their first trimester of pregnancy were supplemented with a mixture of EPO, EPA, and docosahexaenoic acid (DHA) or placebo for six months. Some were treated with magnesium oxide. Participants supplemented with the EPO mixture exhibited significantly better cardiovascular function (reduced incidence of edema, $P < 0.004$) and reduced pre-eclampsia, implying that EPO in combination with EPA and DHA may be helpful in the prevention of pre-eclampsia (83).

Early studies have shown that EPO is an effective natural remedy for some female specific adverse health conditions (2). But more recent studies disagree with some of these findings, showing that EPO exerts no significant change beyond a placebo effect in controlled human trials. More investigations are needed in order to conclusively resolve these discrepancies. In addition, patient assessments should be based on clinical evaluations and not on symptom frequency questionnaires in order to reduce the level of uncertainty in results and increase the significance of experimental findings.

EPO AND DIABETES MELLITUS-INDUCED NEUROPATHY

Insulin is a peptide-based pancreatic hormone that stimulates most body cells to absorb plasma glucose necessary for energy and cellular metabolism. Several mammalian glucose transporters require insulin for activation and cell membrane incorporation (receptor requirement). Diabetes mellitus is a disease caused by a relative or complete lack of insulin action that leads to detrimental alterations in carbohydrate metabolism. "Diabetes mellitus" is Latin for "to flow sweet," which refers to the large volume of urine produced daily with high glucose content. There are two

forms of diabetes mellitus: juvenile onset and adult onset diabetes. Juvenile onset diabetes (Type-I diabetes) is a genetic disease believed to be caused by an autoimmune reaction early in life in which the pancreatic β -cells that secrete insulin into the bloodstream become nonfunctional, thereby causing insulin deficiency that can only be treated with insulin injections; hence, the term insulin-dependent diabetes mellitus (IDDM). Adult onset diabetes (Type-II diabetes), by far the most prominent form, is characterized by normal-to-high β -cell activity and insulin levels but markedly decreased insulin sensitivity and tends to affect obese individuals (84). Both Type-I and Type-II diabetes result in high plasma glucose levels that can alter plasma proteins such as hemoglobin and disrupt microvascular circulation by increasing blood coagulation that may require the amputation of limbs and can lead to neuropathy. Diabetics have been shown to have diminished Δ -5- and Δ -6-desaturase activity, causing alterations in tissue fatty acid profiles and deficiencies in some long-chain PUFA (85). Membrane fatty acid composition is known to affect the cellular response to insulin. Increases in membrane PUFA levels enhance cellular insulin sensitivity and receptor recruitment, while decreasing the levels has the opposite effect, decreased insulin responsiveness (86). Because essential PUFA are known to improve insulin responsiveness at the cellular level, several studies have been done to investigate whether oils rich in PUFA, such as EPO, can improve diabetes management. Most of the investigations on the effects of EPO on diabetes mellitus have been carried out using animal models in which the administration of diabetogenic agents or pancreatectomy is done to induce the disorder. These models closely resemble Type-I diabetes and are particularly useful in the study of diabetic neuropathy.

Vascular changes that occur during diabetes mellitus may cause reductions in nerve perfusion leading to impaired nerve function and neuropathy. Cameron et al. (87) examined whether EPO supplementation could help overcome diabetic nerve conduction deficits in diabetic rats. The animals were treated with streptozotocin (a diabetogenic agent) and fed normal diets for one month to allow for the accumulation of nerve conduction deficits. After this initial feeding period, experimental animals were fed diets supplemented with 10% EPO for one month to assess whether this treatment could reduce the extent of diabetes-induced abnormalities. Control diabetic and nondiabetic rats were fed normal diets for two months. Results of this study showed that after the initial 1 mo feeding period, diabetic rats exhibited deficits in motor and sensory nerve conduction velocity, which were maintained over a two-month period. In EPO-treated diabetic rats, deficits in nerve conduction velocity were restored to the level of nondiabetic control rats (87). These findings suggest that EPO is an effective treatment for diabetes-induced neuropathy in this animal model. More recently, the effects of sunflower oil, EPO, and two structured γ -linolenic acid-containing triacylglycerols were examined on nerve conduction deficits in streptozotocin-induced diabetic rats (88). Animals were fed diets supplemented with sunflower oil, EPO, dilinolein mono- γ -linoleate, or tri- γ -linoleate for six weeks after diabetes induction to examine whether the stereospecific distribution of γ -linolenic acid in triacylglycerols could influence

diabetes-induced neuropathy. All diets were prepared to contain equal amounts of γ -linolenic acid, except for sunflower oil-supplemented diets that served as control diets. Results showed that all three γ -linolenic acid-containing diets restored nerve conduction velocity, while sunflower oil-treated controls showed no such improvements, implying that the stereospecific distribution of γ -linolenic acid in dietary triacylglycerols did not influence its therapeutic effects in this animal model (88). Ford et al. (89) examined effects of treatments with EPO, α -lipoic acid, or sunflower oil on peripheral nerve conduction and vascular parameters in streptozotocin-induced diabetic rats. For six weeks after the induction of diabetes mellitus, the animals were fed normal diets; normal untreated rats were placed on the same diet for use as controls. After the initial feeding period, control and diabetic animals were treated daily with 300 mg/kg body weight α -lipoic acid, 10 g/kg body weight EPO, or 10 g/kg body weight sunflower oil for 27 weeks. EPO treatments for two weeks significantly improved both motor and sensory nerve conduction velocity in diabetic rats ($P < 0.05$ or less) and resulted in the restoration of normal nondiabetic control values in these animals. However, no significant vascular improvements were observed in the EPO-treated diabetic group. α -Lipoic acid treatments resulted in significant improvements in both nerve conduction velocities and vascular parameters in diabetic rats ($P < 0.05$ or less). Sunflower oil-treated diabetic rats showed no significant differences in vascular and neuronal conduction parameters compared to control diabetic rats (89).

Findings from animal models show that EPO is an antineuropathic agent in streptozotocin-induced diabetes and may be of benefit in the prevention of neuropathy in diabetic humans. To date, however, no published trials have investigated the effects of EPO on diabetic neuropathy in humans.

OTHER HEALTH EFFECTS OF EPO

Animal and human studies have investigated the effects of EPO on mental health (90), inflammatory bowel disease (91), and renal health (92). Joy, Mumby, and Joy (90) systematically searched several scientific databases for randomized trials investigating the effects of EPO on schizophrenia. In some trials, EPO supplementation improved symptoms, while others showed no such effects (90). Greenfield et al. (93) showed that EPO treatment improved stool frequency in ulcerative colitis patients after three months of supplementation; no such effects were observed for patients treated with Max-EPA fish oil. Animal studies show that EPO treatments can significantly reduce cyclosporin-A-mediated nephrotoxicity (94,95). Yoshimoto et al. (96) showed that EPO treatments significantly improved skin symptoms and abnormal plasma fatty acid compositions of hemodialysis patients. These health effects of EPO seem promising. However, the amount of existing literature is small making it hard to draw clear conclusions about these effects. Furthermore, most of these studies have been small scale with few having more than 40 subjects; large-scale trials involving humans are needed (Table 1).

Table 1 Summary of Research Findings on the Effects of EPO in Health and Disease

Disease/condition studied	Type of evidence (References)	Overall findings
Atopic dermatitis	Small-scale human trials (30–38)	EPO may be effective treatment for some clinical symptoms
Rheumatoid arthritis	Small- and medium-scale human trials (43–48)	Inconclusive; several trials possess faults in their study protocol
Cardiovascular disease	Animal studies (55–60) and small-scale human studies (61,62)	EPO is effective in animals; no evidence suggests effectiveness in humans
Cancer	In vitro/animal studies (65–68) and small-scale human trials (68)	Animal studies suggest EPO is antiproliferative; some human studies agree
Menopausal hot flashes	Small-scale human trials (72)	Inconclusive findings
Osteoporosis	Small-scale human studies (73)	Ineffective in reducing bone density loss and other markers of osteoporosis
Breast mastalgia	Small-scale human studies (74)	Few studies indicate therapeutic effectiveness
Premenstrual syndrome	Small-scale human trials (78,79)	No clinical evidence of effectiveness
Pregnancy-induced hypertension/pre-eclampsia	Animal studies (81) and small-scale human trials (82,83)	Both animal and human studies implicate EPO as therapeutic
Diabetes mellitus-induced neuropathy	Animal studies (87–89)	EPO is an antineuropathic agent in diabetic animal models

CONCLUSIONS

EPO might modify several health factors that could in turn modify the onset of disease states. It may exert therapeutic effects in inflammatory and immune-mediated diseases, cardiovascular diseases, cancer, and some conditions associated with menopause. These effects may in part be due to the oil's γ -linolenic acid constituent that could promote the production of anti-inflammatory dihomogamma-linolenic acid-derived eicosanoids and/or reduce proinflammatory arachidonic acid-derived eicosanoid production, thus affecting several aspects of cellular biology and physiology such as immune hyper-reactivity, vascular function, and cellular proliferation. However, it is quite possible that some other components or group of compounds present in EPO may be responsible for its health effects. Incorporation into normal human diets would provide adequate levels of γ -linolenic acid and vitamin E, thereby reducing the likelihood of their deficiency. Thus, EPO may exert several beneficial effects on human health and disease states. Nonetheless, further studies are needed before any casual relationships between health/disease states and EPO can be made.

Feverfew

Dennis V. C. Awang

INTRODUCTION

Feverfew (*Tanacetum parthenium*) has been used since antiquity for a variety of medicinal purposes, prominent among them being alleviation of fever, headache, and women's ailments. Claims of efficacy are almost invariably anecdotal. However, over the past two decades, randomized controlled trials have been conducted in the prophylaxis of migraine and treatment of rheumatoid arthritis. While the quality of these trials is varied, there is good evidence of feverfew's potential in migraine: statistically significant reduction in frequency and severity of attacks and degree of nausea and vomiting has been observed following administration of feverfew leaf. While it is said that more people in the U.K. currently self-medicate with feverfew for arthritis than for migraine, no clear benefit has been demonstrated in the single clinical trial conducted with rheumatoid arthritis patients. Neither the constituent(s) of feverfew nor the mechanism(s) of action is/are yet known. Parthenolide, the dominant sesquiterpene lactone (STL) constituent of the clinically tested sesquiterpene chemotype, and long considered the active antimigraine principle, is no longer considered to be a significant contributor in that respect. Also, the latest trial, using a supercritical carbon dioxide extract of feverfew leaf, lends promise to the development of a reliably consistent and effective standardized preparation. No serious adverse reactions have been recorded, although the development of mouth ulcers has caused a small percentage of consumers to discontinue treatment. No drug interactions have been observed so far.

BACKGROUND

Botany

Nomenclature

Following residence in a number of genera after its original assignment to *Rudbeckia* and then *Matricaria* by Linnaeus, feverfew, a member of the plant family Asteraceae (Compositae), is currently recognized as *Tanacetum parthenium* (L.) Schultz Bip. Today, the only previous synonym occasionally encountered in commerce and the scientific literature is *Chrysanthemum parthenium* (L.) Bernh (1).

The most popular common names of this plant are: bachelor's buttons, featherfew, featherfoil (federfoy), flirwort, midsummer daisy, nosebleed, *matricaire*, *grande*

camomille (French), *mutterkraut* (German), *altamisa*, *Santa Maria*, *manzanilla* (Spanish) (2) (Fig. 1).

The generic term *Tanacetum* is claimed to be derived from the Greek word *athanatos*, meaning immortal (*thanatos*, death), which alludes to the ever-lasting nature of the plant's dried flowers. The specific epithet *parthenium* likely originates from the Greek *parthenos*, meaning virgin, apparently in reference to the traditional use by women for menstrual difficulties (3). The common name feverfew is widely held to be a translation of the Latin *febrifugia*, an agent that dispels fever.

Physical Description

The feverfew plant is a strongly aromatic bushy perennial that can grow to 90 cm high. Its crushed leaves are bitter and have a distinctly camphorous odor. The stems (up to 5 mm in diameter) have yellow-green, deeply divided leaves, 2 to 5 cm long, that bear characteristic glandular and covering trichomes (hairs). The wild-type feverfew, traditionally used as medicine, has daisy-like flower heads composed of 5 to 30 functional male and female yellow disc florets, generally 1 to 2 cm in diameter, surrounded by a single row of female ray florets, each with a white corolla 3 to 8 mm long, with a 2 to 7 mm long strap.

Several taxonomic varieties and forms have been recognized on the basis of differences in floral and leaf morphologies. Some of these have two or more rows of ray florets, and at least one is devoid of ray florets (4); two prominent cultivars, *crispum* and *aureum*, have curled leaf edges and decidedly yellow leaves, respectively (5).

Native to the mountains of the Balkan Peninsula, feverfew has spread throughout Europe, to North, Central, and South America, and is now widely cultivated commercially both as a medicinal and as an ornamental plant (6).

Medicinal feverfew is derived mainly from the leaves of the plant, but some countries, such as France, allow inclusion of stalk and flowers (7). Commercial dried feverfew leaf usually contains about 10% of stalk (8). Feverfew leaf extracts are also available.

History

Ancient Uses

The ancient medicinal applications of feverfew have been categorized broadly into three main groups: Treatment for fever and headache; use in cases of difficulties in labor, threatened miscarriage, and regulation of menstruation; and relief of stomachache, toothache, and insect bites (9).

Figure 1 *Tanacetum parthenium* (L.) Schultz Bip. Source: Courtesy of J.S. Peterson, USDA-NRCS PLANTS Database.

Since the time of Dioscorides, the first century Greek physician, feverfew has been used to treat intermittent fevers and has been grown in monastic gardens for that purpose (9). John Gerard(e)'s book, *The Herball*, originally published in 1597 (10), claimed that "(Feverfew) is very effectual for all pains in the head coming of a cold cause, the herb being bruised and applied to the crown of the head." Gerard further added that "Feverfew dried and made into powder, and two drams of it taken with hony or sweet wine, purgeth by siege melancholy and flegme; wherefore it is very good for them that are giddie in the head, or which have the turning called vertigo, that is a swimming and turning in the head. Also it is good for such as be melancholic, sad, pensive, and without speech." Also, Gerard claimed that feverfew was "profitable applied to Saint Antonies fire, to all inflammation and hot swellings." Feverfew has been termed "the aspirin of the 18th century (11)." Culpeper's *Complete Herbal*, originally printed in 1649 (12), recommended feverfew for "ague" (fever with chills): "the decoction drank warm, and the herb bruised, with a few corns of bay-salt, and applied to the wrists before the coming of the ague fits, does take them away." In support of effectiveness against stomachache and insect bites, a very early herbal, Bancke's (1525), is quoted by Berry (9): "This is named Federfoy. His virtue is to conforte a mannus stomake. It is good to asswage the axes cotydan, ye crampe, and to tempre it that cometh of colde stomackes. Also it is good to lay to a soore that is byten with venymous beestes; it will hele it shortly on it be layde thereto." Regarding toothache, Charles Estienne declares: "Stampd and applied unto the teeth or eare of the side that aketh, it wholly asswageth the paine of the teethe (13)."

As noted earlier, the third major area of traditional medicinal application of feverfew deals with "female complaints." Regarding its usefulness as an emmenagogue, assisting and promoting menstrual flow, Gerard (10) states: "... it procureth womens sickness with speed, it bringeth forth the afterbirth and the dead child..." According to

Culpeper (12), "Venus commands this herb, and has commended it to succour her sisters to be a general strengthener of their wombs, and to remedy such infirmities as a careless midwife has there caused; if they will be pleased to make use of her herb boiled in white wine, and drink the decoction, it cleanses the womb, expels the after-birth, and does a woman all the good she can desire of a herb."

As a final note on the traditional use of feverfew for headache and claims by some authors as to its ancient use in migraine (9) and specifically "for the prevention of migraine" since the time of Dioscorides (AD 50) (14), the often cited opinion of John Hill, M.D., recorded in 1772 in his book *The Family Herbal* ("In the worst headache this herb exceeds whatever else is known") (11), has been interpreted as a reference to migraine. However, it is highly questionable whether the characteristic features of migraine were appreciated then and whether feverfew's migraine prophylactic potential was recognized. Feverfew's antimigraine effect was discovered in modern times only in 1973 (15), and it has been widely held that feverfew's influence is entirely prophylactic and not in the realm of symptomatic relief. However, a prominent researcher in the field has reported that the housekeeper of a retired British professor of physiology experienced dramatic relief from a migraine attack: within 20 to 30 minutes of chewing five leaves, "her pain had vanished (16)." Of course, any such anecdotal claim of efficacy, whether ancient or modern, cannot be taken as proof of medicinal value.

Modern Uses

Feverfew is currently widely used to mitigate migraine attacks, as a palliative in arthritis, and for the treatment of psoriasis (17). However, while it is claimed that, since the 16th century, feverfew has been used by more people in the U.K. for arthritis than for migraine (11), most of the research attention has been focused on the latter condition (see clinical studies). The dramatic upsurge of interest in feverfew for migraine occurred following newspaper accounts of favorable responses in sufferers whose condition was resistant to conventional medication (11). The stimulus for this burgeoning attention was the experience of Ann Jenkins, a Welsh doctor's wife, who in 1973 at age 68, upon the suggestion of the elderly father of a friend of her sister's, had begun experimenting with feverfew; the old gentleman, interestingly enough, had found feverfew helpful in treating his arthritis. After increasing the dose from one small leaf to three, after five months, the vomiting associated with the migraine attacks stopped. She also required less of her conventional migraine treatment, ergotamine. After 6 months, she went for an entire month without a migraine attack, and after 10 months, the attacks ceased (15).

The Questionnaire

With the assistance of Mrs. Jenkins, Dr. E. Stewart Johnson, associated with the City of London Migraine Clinic, solicited participants in an epidemiological survey on the use and value of feverfew. A questionnaire was provided inquiring as to whether headaches during use of the herb were less frequent, more frequent, less painful,

more painful, or unchanged. Of the roughly 300 responders, 253 were judged to be suffering from true migraine, 93% having been diagnosed by a doctor. Of these, 72% reported reduced frequency of migraine attacks, while 26% felt that their headaches worsened. This success rate was virtually identical for participants whether or not they were suffering from other ailments or taking other medications. A further assessment of 242 patients for actual numbers of attacks each month before and during feverfew treatment revealed that 33% no longer suffered any migraine attacks while taking the herb and 76% had fewer monthly episodes. Eighty percent of those who stopped taking feverfew reported recurrence of severe migraine within a week or two. A polling of feverfew users on their experience with conventional migraine-preventive drugs produced very interesting results. Clonidine, the pharmaceutical most commonly tried, was deemed ineffective by 72% of feverfew users, while ergotamine, the most helpful of the other drugs, was judged helpful by 62%. Most of the other drugs were found less than 50% effective. Curiously, about 40% of feverfew users attributed pleasant side effects to the plant: relief from the symptoms of coexisting arthritis, less muscular tension, more restful sleep, and the like. Responders to the questionnaire had been taking feverfew for an average of two-and-a-half years (15). Traditionally, feverfew users take two to four small or one to two large leaves per day, often in a bread and butter sandwich, sometimes mixing honey with the crushed leaves to further mask the bitter taste (11).

CHEMISTRY

The main chemical constituents that have received attention regarding biological activity fall into three categories, namely, essential oil, STLs, and flavonoids. The flavonoids of feverfew are the lipophilic flavonols di- and trimethylethers of 6-hydroxykaempferol and quercetagenin, and the hydrophilic flavone glycosides apigenin-7-glucuronide, luteolin-7-glucuronide, and chrysoeriol-7-glucuronide (18). The trimethylether of 6-hydroxykaempferol, originally named tanetin, and characterized as 3,7,4'-substituted, was later determined to be the known flavonol santin, a 3,6,4'-trimethylether. Santin, 6-hydroxykaempferol-3,6-dimethylether, and quercetagenin-3,6-dimethylether (axillarin) are the three main flavonol constituents. Two further minor lipophilic flavonols have been identified unequivocally: quercetagenin-3,6,3'-trimethylether (jaceidin) and quercetagenin-3,6,4'-trimethylether (centaureidin) (19).

The volatile essential oil is dominated by camphor (43–44%) and chrysanthemyl acetate (24%), accompanied by lesser amounts of spiroketal enol ether diynes, camphene, germacrene-D, *p*-cymene and terpinen-4-ol. The dominant STL, parthenolide, is also released in the volatile oil, as are the ubiquitous phytosterols, sitosterol, and stigmasterol (20–22). No significant infraspecific variation has been observed in the composition of the volatile oil (23) (Fig. 2).

STLs have until recently been the prime focus of chemical and biological attention among feverfew constituents. The germacranolide (10-membered carbon ring), parthenolide, dominates the STL chemotype that has been

Parthenolide

trans-Chrysanthemyl acetate

Isomeric spiroketal enol diynes

Figure 2 Some bioactive constituents of *Tanacetum parthenium*.

subjected to clinical evaluation. The most comprehensive analysis of the chemical content of feverfew leaf has been conducted by Bohlmann and Zdero (24). Parthenolide comprises more than 80% of the total STL content of this chemotype, in concentrations as high as 2% of dry weight in individual plants (25). At least two other STL chemotypes of feverfew have been recognized, devoid of parthenolide (26). The most prominent STLs accompanying parthenolide in the clinically efficacious STL chemical profile are 3 β -hydroxy parthenolide, the isomeric guaianolide (5/7-carbocyclic) *bis*-epoxides, canin (α) and artemcanin (β), the endoperoxide precursor of canin, tanaparthin- α -peroxide, and the cyclopentenone *seco*-tanaparthinolide A, all containing an α -methylene- γ -butyrolactone moiety (16,27). Canin and artemcanin also occur in a Mexican chemotype devoid of parthenolide, in which the eudesmanolides reynosin and santamarin are prominent (16).

Respecting the historical identification of feverfew STLs, it should be noted that there is a serious question

concerning the presence of unusually structured compounds such as chrysanthemonin, chrysanthemolide, and partholide (28), which are not identified elsewhere as feverfew constituents and are likely the result of degradation during protracted refluxing for one week and subsequent processing; chrysanthemonin, a trisesquiterpene species, has been described as (29) "a novel dimeric germacranolide nucleus, esterified at C-8 by a related esterified sesquiterpenic acid." Likewise probably artifactual are the chlorine-containing STLs reported from *T. parthenium* extracted from the same material with chlorinated solvent; the two isomeric chlorohydrins in question were not detected by Hylands, at the University of London, who provided the feverfew leaf, and almost certainly resulted from epoxide ring opening by hydrogen chloride present in the chloroform used for extraction (30). One of the two chlorides, characterized by X-ray analysis, is formally an adduct chlorohydrin formed by β -chloride opening of the α -3,4-epoxy function of canin. The structure of the other isomer, uncrystallized, has not been confirmed, but the proposed C-10 epimerized configuration seems extremely unlikely, not having ever been observed in any feverfew STL.

CLINICAL STUDIES

Migraine

Of the six clinical trials reported, results on one (31) are available only by way of an abstract, which provides neither information on the nature of the tested material nor adequate details about outcome measures. Nonetheless, a systematic review of these trials has accorded it a rating on the Jadad (32) scale of judging quality (33). Of the other five trials, three with dried whole leaf preparations and two with extracts, four are positive. One of the studies that used extract provided a negative result of singular importance (34).

The first of the positive trials, a randomized double-blind and placebo-controlled study (35), involved only 17 patients and has been properly criticized not only on the basis of its small size, but also because the subjects were self-selected, being convinced of the efficacy of feverfew from their history of beneficial self-medication for roughly three to four years and the corresponding expectation of relapse attendant on deprivation of the medicine. In this four-month-long study, eight and nine subjects, respectively, received a daily dose of 50 mg of freeze-dried feverfew leaf powder or placebo. Those who took placebo had a significant increase in both frequency and severity of migraine attacks as well as of nausea and vomiting during the early months of feverfew withdrawal. Two subsequent trials, conducted in the U.K. (36) and Israel (37), used encapsulated air-dried feverfew leaf powder. The British trial was of a randomized, double-blind, placebo-controlled crossover design. After a one-month single-blind placebo run in, 60 patients were randomly allocated to a daily capsule of the treatment (70–114 mg; mean 82 mg) or matching placebo (dried cabbage leaves) for four months and then switched for a further four months. Results on 59 patients were analyzed and revealed feverfew to be associated with a reduction in the mean number and severity of attacks as well as in the degree of vomiting. In the

Israeli trial, 57 patients were divided into groups of 30 and 27 after a preliminary two-month treatment with feverfew (100 mg daily), following which a double-blind placebo-controlled crossover study was conducted in two phases over two months each. As with the earlier British trial, a significant reduction in pain intensity was observed as compared with placebo—as was a "profound" reduction in typical migraine symptoms such as vomiting, nausea, and sensitivity to noise and light.

Two trials have been conducted with extracts of feverfew leaf, one a failure (34) and the other a limited success (38). The earlier trial with 90% ethanol extract was judged to be methodologically of superior quality (33) but revealed no difference between placebo and the treatment, which contained roughly twice the level of parthenolide as the feverfew treatment used in the successful Israeli trial (37). These observations impose the unavoidable inference that parthenolide cannot be directly responsible for feverfew's antimigraine activity. The ineffectiveness of this extract preparation was likely due to loss or degradation of the active principle(s) as a result of the protracted extraction process, involving stirring in solvent for 19 days at ambient room temperature (34). The final trial employed a proprietary supercritical carbon dioxide extract of feverfew leaf in a randomized, double-blind, placebo-controlled multicenter trial with four parallel groups receiving daily doses of 2.08, 6.25, and 18.75 mg for 12 weeks. While the proprietary preparation failed to exert a significant migraine prophylactic effect in general, it was safe and effective at 6.25 mg thrice daily in a small subgroup of patients with at least four migraine attacks per month. The authors of this last study cautioned that their findings should be regarded with reservation on account of the small number of subjects. These German researchers have completed another trial, which supported the findings of the initial study (39).

Arthritis

A single clinical trial in rheumatoid arthritis failed to show any beneficial effect in 40 women treated with 70 to 86 mg of dried feverfew leaf or placebo for six weeks (40). However, considering the continued popularity of the plant for treating the symptoms of this condition, it has been suggested that it may well be of benefit in milder cases of arthritis than that afflicting the women in this trial, who were extremely refractory cases and unresponsive to all conventional arthritis drugs. The authors of the failed trial suggested further that feverfew may be of benefit in osteoarthritis and for soft tissue lesions (40).

Mechanism of Action

The simplistic mechanism of feverfew action in migraine, involving Michael addition of systemic nucleophiles to α,β -unsaturated lactones such as parthenolide and inhibition of the release of serotonin (5-hydroxytryptamine, or 5-HT) from blood platelets, is now totally discredited (41). It seems likely that the feverfew constituent(s) responsible for its antimigraine activity will be found in the volatile fraction of the plant's leaf. However, the relevance of any of the plethora of *in vitro* pharmacological activities noted in both aqueous and organic extracts of feverfew leaf (16,17) has not been established. Nonetheless,

inhibition of the release of damaging substances from white blood cells in inflamed joints and skin could account for the claimed benefit of feverfew in arthritis and psoriasis (17).

Migraine Prophylaxis

Of the three main categories of feverfew chemical constituents demonstrated to possess biological activity, most attention has been directed toward STLs, especially parthenolide. However, as noted above, the ineluctable inference from the failed Dutch trial would seem to be that parthenolide is not a significant contributor to the antimigraine effects of feverfew leaf. No flavonoids have been reported in the efficacious antimigraine supercritical carbon dioxide fluid extract of feverfew leaf (38,39). The Dutch scientists who conducted the unsuccessful trial of a 90% alcoholic extract of feverfew leaf (34) noted that the content of an essential oil component, *trans*-chrysanthenyl acetate, had declined from 0.25% in the leaf raw material, to 0.017% in the phytotherapeutic preparation, suggesting to them a possible relationship to the observed inefficacy of their preparation. However, though evaporation of volatile components of the essential oil may have been somewhat of a contributing factor to loss of activity, degradation of active principle(s) over the protracted period of digestion of the leaf material, is more likely to be the main basis of inactivation (42).

Feverfew essential oil contains, in addition to parthenolide, two other dominant constituents, namely camphor and *trans*-chrysanthenyl acetate, along with lesser amounts of isomeric spiroketal enol ether diynes (42). These last isomers have been identified both in the German proprietary carbon dioxide extract (percentage unspecified) (22) and in ether extracts of feverfew flower heads (*trans*: 6.1%) and root (*cis*: 57.5%, *trans*: 5.1%, and a pyran analog of *trans*: 7.5%) (21). In the flower head extract, parthenolide, camphor, and *trans*-chrysanthenyl acetate represent 28.4%, 18.9%, and 15.5% of total extract content, respectively; though these compounds were present in the leaf extract at 6.1%, 20.1%, and 4.7%, respectively, they were not detected in the root extract. Other prominent components of the root extract are a pair of triterpenoids (19.9%), one an alcohol and the other tentatively identified as D-friedoolean-14-en-3-ol (5.3%). Chrysanthenyl acetate, like parthenolide, is known to inhibit prostaglandin synthetase and to have analgesic properties (19). Testing of an ether extract of feverfew root for antimigraine activity should be revealing since the extract is free of chrysanthenyl acetate, parthenolide, and flavonoids.

Though the antimigraine activity of feverfew was originally thought to be due to inhibition of production of inflammatory platelet-aggregating prostaglandins, later studies revealed a prostaglandin-independent effect different from that obtained with other inhibitors of platelet aggregation, such as nonsteroidal anti-inflammatory drugs, such as aspirin (43).

The spiroketal enol ether diynes are potent insect and antifeedant compounds, and are also present in *Chrysanthemum segetum* (corn marigold) (44) and *Matricaria recutita* (German chamomile), of which the *cis* isomer was shown to exert a spasmolytic action at least 10

times as great as that of papaverine (45). Enol ethers in contrast to saturated ethers, are very susceptible to acid-catalyzed hydrolysis. The aqueous alcoholic Dutch extraction medium (34), rendered acidic by the presence of long-chain fatty acids, such as arachidic, linolenic myristic, oleic, palmitic, and stearic acids, could provide an environment conducive to such degradation—disruption of the extended diyne-diene conjugation by conversion of spiroketal enol ether to hydroxyketone can be expected to have a significant effect on extract activity.

SAFETY

Adverse Effects

No serious adverse effects have been reported for feverfew consumption. The side effect that has received the most attention is mouth ulceration, the formation of recurrent, so-called aphthous ulcers (commonly referred to as “canker sores”). Interestingly, in the University of Nottingham trial (36), more patients (16) in the placebo group reported mouth ulceration than those in the verum group (10). Johnson (15) had previously noted that 11.3% of the 253 patients participating in a questionnaire survey admitted to experiencing mouth ulceration when asked but only 6.4% volunteered such information; a parallel situation was obtained for indigestion, with 6.5% and 3.9%, respectively. It is also interesting to note that mouth ulceration from feverfew appears to be a systematic effect that resolves within a week or so of discontinuation of the treatment, but returned on rechallenge. It has been claimed that the mouth ulceration can be alleviated by treatment with tincture of myrrh (normally derived from *Commiphora* species, especially *Commiphora molmol*) (46). Nonsteroidal anti-inflammatory drugs (NSAIDs), increasingly used for migraine prophylaxis and arthritis, also produce recurrent aphthous ulceration (47). Feverfew sometimes induces a more generalized inflammation of the oral mucosa and tongue, with attendant swelling of lips and loss of taste. This soreness is likely caused by direct contact with leaves during chewing and probably due to the interaction of STLs known to cause contact dermatitis (48).

Feverfew leaf does not appear to affect blood pressure, heart rate, body weight, or the results of hematological and biochemical tests, but rare cases of transient palpitations, colicky abdominal pain, and heavier menstruation have been reported (35).

Also, a “post-feverfew syndrome” has been identified in long-term feverfew users who stopped taking the herb. About one-tenth experienced moderate-to-severe aches, pains, and stiffness in joints and muscles, along with CNS symptoms of anxiety and poor sleep (35). It has been speculated that such sleep disturbances may be due to withdrawal of melatonin, present in significant quantities in the leaf (2.45 µg/g in fresh; 2.19 µg/g in dried) (49).

Toxicology

While no formal studies have been conducted to assess chronic toxicity in animals, it has been argued that such tests are now superfluous since feverfew has been used by large numbers of people continuously for many years,

some for more than 10 years, without apparent ill effect (35).

A study involving 30 females who had been consuming feverfew for more than 11 months revealed no differences in the frequency of chromosomal aberrations or the frequency of sister chromatid exchanges compared with a matched set of nonusers (50).

Contraindications

In view of feverfew's traditional reputation as an emmenagogue, its capacity to induce uterine contraction in full-term women, and its ability to cause abortion in cattle, it would seem prudent for pregnant women to avoid its use. It should also be noted that when feverfew was used to promote menstruation, it was taken in much higher doses than those currently employed for treating migraine and arthritis. Finally, little is known of the effects of feverfew on migraine and arthritis in pregnancy (15).

Feverfew is also contraindicated in persons with recognized hypersensitivity to other members of the Asteraceae, since crossreactivity is common among plants in this family (51).

Drug Interactions

Feverfew is often indicated by certain scientists as an anti-coagulant herb, based on the ability of parthenolide, only one of its numerous biologically active constituents, to inhibit platelet aggregation. Yet, neither bleeding episodes nor abnormal coagulation tests have been reported from feverfew use (52).

Flaxseed

Lilian U. Thompson and Julie K. Mason

INTRODUCTION

Flax (*Linum usitatissimum*) or linseed is an ancient crop, which has been grown for fiber (linen) and nutritional and industrial use. Although flax is used for these purposes belong to the same *Linum* species, they differ in varieties. In Europe, “flax” is the term often used to describe the crop used for fiber and “linseed” is the term for nutritional and industrial use (1). In North America, the terms “linseed” and “flax” are used interchangeably, however, there is preference for the use of “flaxseed” term when referring to the seed for human consumption. In this chapter, the term “flaxseed” will be used to refer to the seed and “flax” to refer to the plant.

Flaxseed is a dietary supplement or ingredient increasingly being used by consumers for its perceived health benefits. This chapter will provide information on flaxseed—its production, composition, health beneficial effects including in cardiovascular disease (CVD), breast, prostate, and colon cancer, bone health and menopausal symptoms, and safety, as observed in animal, clinical, and epidemiological studies, and mechanisms of action. The physiological roles of its major bioactive components, n-3 fatty acid-rich flaxseed oil and lignans, taken as dietary supplement or as part of flaxseed, will be discussed. Regulations in the use of flaxseed are also described.

BACKGROUND

As previously reviewed, flax is an ancient crop dating at least 8000 years ago in Syria, Turkey, and Iran (1). Domestication started around 7000 BC and, based on archeological findings, linseed oil appears to have been used for embalming and the linen for fabric for Egyptian cloth. Around 1000 BC, flaxseed was used in breads in Jordan and Greece and later on as laxative. In Ethiopia, flaxseed was used in stews, porridge, and drinks, sometimes roasted and mixed with pulses. It is believed that French immigrants brought flax to North America around AD 1600. Early use of flax in North America was for fiber in the linen industry and for oil in paints and linoleum industries. Interest in the use of flaxseed as a food started around 1980s and as a functional food in the 1990s.

While the origin of flax is near the Middle East, flax is currently grown in over 30 countries with the main producers being Argentina, Canada, China, India, Poland, Romania, Russia, Uruguay, and USA; Canada is the leading producer and exporter. In temperate climate areas, flax

is a summer annual crop although winter annual crop has also been grown in some European countries with mild winters. Flax varieties grown for linen are different from those used for food.

There are anecdotal evidence of efficacy and safety of flaxseed. Around 500 BC, Hippocrates wrote about its use in reducing abdominal distress, as a laxative and poultice (1). Raw flaxseed was boiled in water and the solution was drunk to serve as a stool softener. Around the eighth century AD, the emperor of the West (Charlemagne) considered flaxseed as healthful and he passed laws and regulations requiring flaxseed consumption by his subjects. Flaxseed-containing drink was used in Ethiopia to reduce itching with the effect attributed to its oil content. In North America, pioneers made flaxseed poultices for treating cuts and burns. Certain flaxseed varieties were used as well for eyewash, coughs, gallstones, lung and digestive disorders including constipation. Although flaxseed has been used for various illnesses and disorders in the past, it is only in recent years that scientific studies demonstrating the efficacy of flaxseed have been conducted.

CHEMISTRY AND PRODUCTS

Flaxseed

Cultivated flaxseed varies in composition depending on cultivar, growth location, and environmental conditions but its typical composition is shown in Table 1 (2–4). Of interest and the main reason for its use as dietary supplement or ingredient for health benefits, however, is its high amount of oil rich in the n-3 fatty acid, α -linolenic acid (ALA), the high amount of dietary fiber, and the phytoestrogen called lignans, in addition to its high-quality protein. Flaxseed also contains tocopherols and many phenolic acids including ferulic, coumaric, caffeic, chlorogenic, gallic, protocatechuic; *p*-hydroxybenzoic acid, sinapic acid, and vanillic acid. Since phenolics have antioxidant properties, they may also contribute to the potential health benefits of flaxseed. A concern is the presence of antinutritional factors such as the cyanogenic glucosides primarily linamarin, linustatin, and neolinstatin, which produce toxic hydrogen cyanide when hydrolyzed. It can be removed from the seed by solvent extraction (e.g., alkanol-ammonia-water-hexane) or heating (e.g., microwave, autoclaving, oven heating, extrusion, water boiling). Other antinutritional factors include phytic acid, which can bind minerals and make them less bioavailable, and vitamin B6 antagonist (linatine), which

Table 1 Composition of Flaxseed (2–4)

Macronutrient components		Micronutrient/phytochemical components	
Component	Per 100 g	Component	Per 100 g
Sugars (g)	<1.0–2.0	Lignans (mg)	
Dietary fiber (g)	30.5–36.8	Secoisolariciresinol	375.32
Soluble (g)	9.2–11.0	Matairesinol	0.15
Insoluble (g)	21.3–25.8	Lariciresinol	2.81
Fat (g)	39.8–45.6	Pinoresinol	0.73
Fatty acid (% of total)		Cyanogenic glycosides (mg)	
Lauric (C16:0)	4.8	Linamarin	13.8–31.9
Stearic (C18:0)	3.6	Linustatin	213–352
Oleic (C18:1)	21.0	Neolinustatin	91–203
Linoleic (C18:2)	22.8	Phytic acid (mg)	23–33
α -Linolenic (C18:3)	57.4	Tocopherols (mg)	
Protein (g)	17.4–24.1	α -Tocopherol	0.0–1.2
Amino acids (g)		β -Tocopherol	2.4
Alanine	0.99–1.05	γ -Tocopherol	8.5–39.5
Arginine	1.88–2.04	δ -Tocopherol	0.2–1.1

Proline	0.78–0.82	Niacin (B3)	1.4–5.5
Serine	0.88–1.07	Pantothenic acid	1.5–7
Threonine	0.82–0.88	Pyridoxine (B6)	0.4–10
Tryptophan	0.29–0.32	Ascorbate (C)	1.3
Tyrosine	0.51–0.55	Folate	278
Valine	1.17–1.25	Cyanocobalamine (B12)	0–0.5

can lead to vitamin B6 deficiency and poor growth but can be removed by alcohol extraction. Flax absorbs cadmium, which can translocate to the seed and the amount of which varies with varieties and growth location. Accumulation of cadmium in the human kidney can result in renal dysfunction.

Most flaxseed varieties are brown in color except one variety (Omega), which has yellow color; these varieties have very similar macronutrient composition. Solin variety is also yellow colored but is genetically developed to contain low ALA (2–3%) and should not be confused with the high ALA (>50%) Omega variety.

Flaxseed structure consists of the embryo or germ, a thin endosperm and two cotyledons encased in a seed coat called the spermoderm (3). Approximately 55% of the hand-dissected seed is the cotyledon, 36% is the hull (seed coat and endosperm), and 4% is embryo. Most of the oil in the seed (75%) is present in the cotyledon, with 22% in the seed coat and 3% in the embryo. In contrast, a greater proportion of the lignans and dietary fiber are found in the hull.

Flaxseed is commercially available for food as either whole or ground (milled) seed or partially defatted meal. In recent years, flaxseed has also been processed by abrasive milling to separate the hull from the cotyledon fraction. The hull fraction is now being sold as a lignan concentrate containing approximately 4% to 5% lignan for

use as dietary supplement or ingredient, while the cotyledon fraction is sold as a low fiber, high n-3 fatty acid oil-containing ingredient. Whole or ground flaxseed has been incorporated in food products including bakery, pastas, breakfast cereals, nutribars, and dairy products (2).

Flaxseed Oil

Flaxseed oil is comprised primarily of neutral lipids (acylglycerols and fatty acids) (96%) and some polar lipids (glycolipids and phospholipids) with more than 50% of its fatty acid as ALA, an essential n-3 polyunsaturated fatty acid (PUFA) (Table 1) (2,3). Flaxseed is the richest plant source of ALA. ALA cannot be synthesized de novo in mammals and therefore is available only through dietary sources, such as flaxseed and flaxseed oil, perilla oil, canola oil, and soybean oil. ALA is metabolized to the longer chain n-3 fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) through an alternating series of elongation (addition of two carbons) and desaturation (double bond insertion) reactions via $\Delta 6$ and $\Delta 5$ desaturases (5) (Fig. 1). Both EPA and DHA can be metabolized by lipoxygenase, cyclooxygenase, and cytochrome P450 enzymes to produce anti-inflammatory mediators including neuroprotectin D1, E and D series resolvins, and 3-series prostaglandins. The n-6 PUFA, that is, linoleic acid (LA) is metabolized by the same enzymes as n-3 PUFA to form arachidonic acid (AA), a precursor of

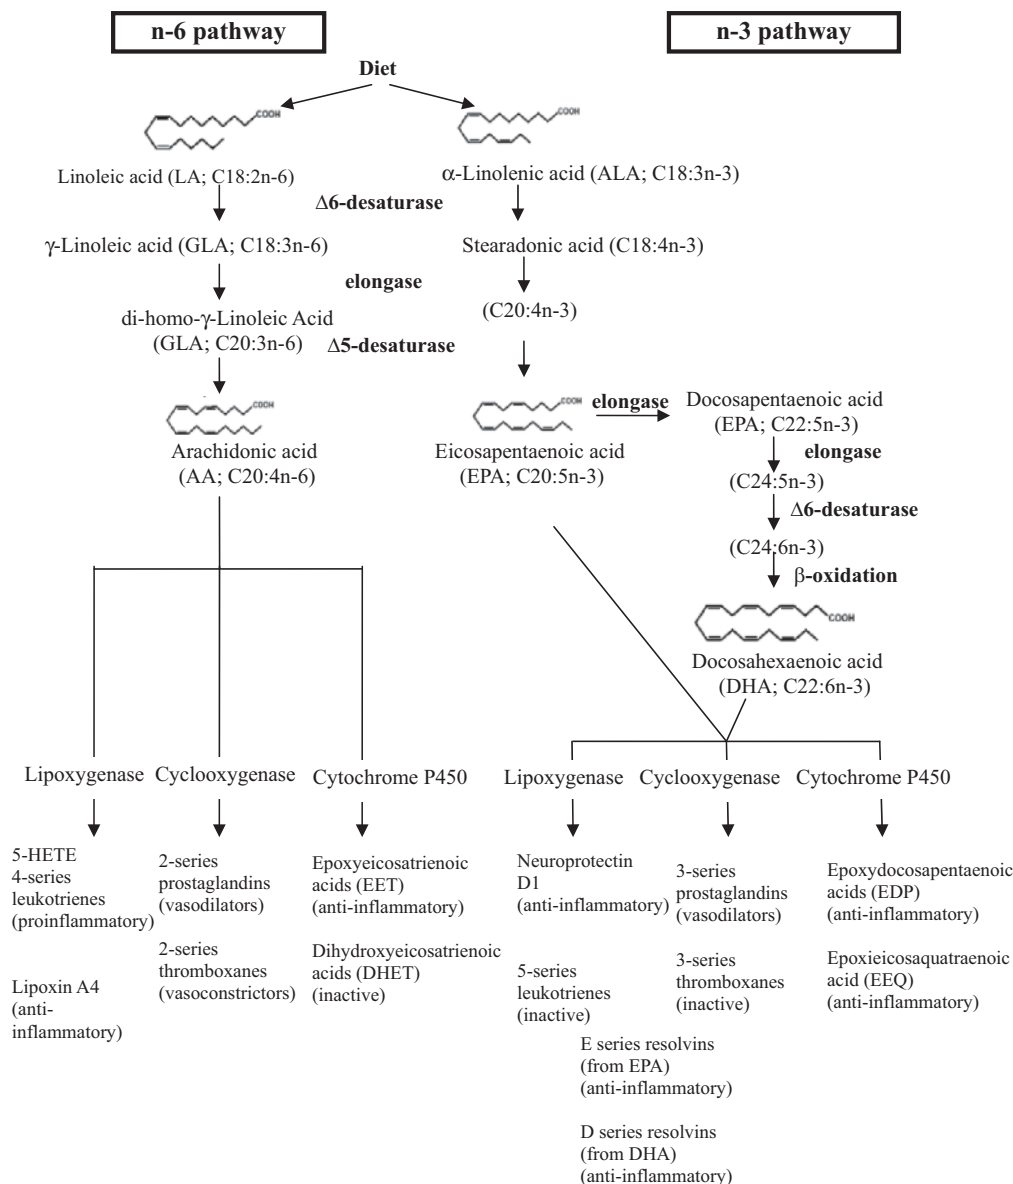

Figure 1 Metabolism of n-3 fatty acid (α -linolenic acid) compared with n-6 fatty acid (linoleic acid).

inflammatory eicosanoids including the 4-series leukotrienes and 5-hydroxyeicosatetraenoic acid (HETE) (Fig. 1). Since n-3 and n-6 PUFA metabolism occur in a competitive fashion, a high intake of n-6 fatty acid reduces the conversion of ALA to EPA and DHA. Therefore, for beneficial health effects of n-3 fatty acid-rich diets, reduction of AA synthesis and increasing the n-3/n-6 fatty acid ratio are desirable.

Recent reviews on ALA conversion to longer chain n-3 PUFA consistently showed an increase in plasma EPA with ALA supplementation and no significant increase in DHA levels (6,7). Studies have shown a <0.3% to 8% and up to 21% conversion of ALA to EPA in men and women, respectively. The conversion through to DHA is even lower at <4% but often undetectable in men and up to 9% in women (8). This variability may stem from

the influence of factors such as energy balance and the presence of other dietary factors such as n-6 fatty acids and cofactors influencing desaturation-chain elongation. The physiological action of ALA is not yet fully established but since most of it is catabolized for energy (8), its action may be due to its direct effect or through its longer-chain metabolites.

Lignans

Lignans are compounds derived from the coupling of cinnamic alcohol residues. They are phytoestrogens and those found in foods include secoisolariciresinol, matairesinol, pinoresinol, syringoresinol, lariciresinol, hydroxymatairesinol, medioresinol, and sesamin. Lignans are present in most plant foods but flaxseed is the richest source with the level more than 100 times higher than in

Figure 2 Metabolism of lignans.

other plant foods (2–4,9). Approximately 95% of the lignan in flaxseed is secoisolariciresinol diglucoside (SDG) with matairesinol, pinoresinol, and lariciresinol present in small amounts. In flaxseed, SDG is esterified with 3-hydroxy-3-methylglutaric acid forming an oligomer referred to as lignan complex or polymer. It is also linked to other phenolic acids, such as glucosylated coumaric, caffeic, and ferulic acids. SDG can be extracted from flaxseed using aqueous alcohol and methods are available for producing products containing approximately 40% SDG (2,3,10). Some of these extracts are now commercially sold for use as dietary supplements or food ingredients.

The lignans are metabolized by the colon microbiota into the mammalian lignans (enterolignans) called enterolactone and enterodiol (3,11,12) (Fig. 2). Pinoresinol is metabolized to lariciresinol then to secoisolariciresinol and finally to enterodiol and enterolactone. Matairesinol, which can also be formed from secoisolariciresinol, is metabolized directly to enterolactone. Some of the intestinal bacteria responsible for the conversions have been identified (3,12) (Fig. 2). After the formation, enterolignans are absorbed in the colon into the bloodstream or excreted in the

feces. Enterolignans undergo enterohepatic circulation, that is, they are excreted through the bile duct to the intestines, further metabolized in the colon and reabsorbed. A portion of the enterolignans is excreted in the urine primarily as glucuronide conjugates with small amounts as sulfate conjugate or free. Nine hydroxylated metabolites of enterolactone and enterodiol, produced in the liver, have been reported in the urine after the intake of flaxseed but these accounted for only <5% of the total urinary lignan excretion. The serum and urinary levels of lignans are related to plant lignan intake and thus have been used in studies to indicate plant lignan or flaxseed intake. The conversion of plant lignans is dependent on microbiota activity, thus the conversion to enterolignans differs with the study participant's dietary habits and lifestyle, and is reduced by antibiotic intake (11). Urinary lignan excretion is directly related to flaxseed intake up to 25 g/day (13).

Because of its hard seed coating, whole flaxseed has low lignan availability that is increased two- to fourfold when flaxseed is crushed or milled (14). However, the availability of lignans in flaxseed nutrition bars was similar to those observed with ground seed because of the

extensive chewing of the flaxseed bar before swallowing (15). Based on urinary lignan excretion after the intake of flaxseed, processing of ground flaxseed into bread or muffins does not appear to affect the lignan availability (13). However, based on SDG analysis, recovery of added SDG in breads was reported to be only 73% to 75% after baking (2).

HEALTH BENEFITS

Cardiovascular Disease

Flaxseed has high ALA, lignan, and soluble fiber contents that can potentially protect against CVD. They may play a role through their effect on blood lipid levels, oxidative stress, inflammation, endothelial function, arrhythmia, and atherosclerosis, which have been demonstrated in animal and human studies (Table 2).

Animal Studies

As previously reviewed, dietary flaxseed's effect on atherosclerosis and hence CVD has been explored using animal models including the hypercholesterolemic rabbit and the cholesterol fed, low-density lipoprotein receptor (LDLR^{-/-}) deficient mouse (10). In both animal models, flaxseed feeding has been shown to suppress the development of atherosclerosis, but there is less clarity in the effect on blood lipids. Dietary flaxseed prevented the increase in triglycerides (TGs) in the cholesterol-fed rabbits; however, it had no effect on TG levels in the mouse model. On the other hand, flaxseed showed no effect on cholesterol levels in the rabbit model yet showed a strong protective effect in the mouse model.

Studies have looked into which component of flaxseed may be responsible for its antiatherogenic and lipid lowering effects (10). CDC flaxseed (Crop Development Center, type II flaxseed) with similar composition as ordinary flaxseed but with reduced ALA content (2–3%) fed to hypercholesterolemic rabbits caused a 69% suppression in the development of atherosclerosis with no effect on serum lipids. Flaxseed oil-rich diets (5% in diet, equivalent to 7.5 g/kg/day flaxseed) did not suppress the development of hypercholesterolemic atherosclerosis in rab-

bits nor did it cause any differences in serum lipids. SDG supplementation (15 mg/kg body weight/day) for eight weeks significantly reduced total cholesterol (TC), low-density lipoprotein cholesterol (LDL-C), and TC/high-density lipoprotein (HDL-C). Overall, these suggest that flaxseed can reduce blood lipid and cholesterol levels and atherosclerosis in hypercholesterolemic animals and this effect may be attributed to the lignan component or other components such as the dietary fiber and not to the flaxseed oil.

Clinical Trials

The animal study findings are in agreement with the effect of flaxseed intake on blood lipids in clinical trials recently reviewed (10). Flaxseed consumption (10–50 g/day) in both healthy and hypercholesterolemic individuals have been found to reduce serum TC and LDL-C levels by 1.6% to 18% with no significant effect on levels of HDL-C or TG. There was, however, variability as there are studies that also showed no effect on TC or LDL-C. Meta-analysis of 28 clinical trials of flaxseed or flaxseed component effect on blood lipid profile also showed a reduction in TC and LDL-C with flaxseed intervention and no effect on HDL-C or TG concentrations (16). The effects depend on the form of flaxseed used, study quality, sex, and initial lipid profile, with greater effects in hypercholesterolemic and less or no effect in normocholesterolemic subjects. Further analysis showed that both whole (milled) flaxseed and lignan extract supplementation significantly improved TC and LDL-C levels while flaxseed oil intervention caused no significant change. ALA, on the other hand, has been shown in a clinical trial to have beneficial effects in coronary heart disease (CHD). The Lyon Diet-Heart Study, a secondary prevention trial, found that the ALA-rich Mediterranean type diet caused 70% reduction in subsequent adverse cardiac events in patients who previously suffered myocardial infarction compared with the prudent diet resembling the American Heart Association diet (17).

Epidemiological Studies

A review of several large epidemiological studies has suggested the beneficial effects of ALA in CHD (3). Three large prospective studies have shown a protective role of ALA

Table 2 Biomarkers Indicating Potential Mechanisms Whereby Flaxseed and Its Components Modulate Cardiovascular Disease

in CHD event. The Health Professionals study and the Nurses Health study each followed subjects over six years and found that ALA was the only fatty acid associated with the reduction in nonfatal and fatal CHD, respectively (18,19). Interestingly, EPA and DHA were not associated with heart attack risk indicating that their effects on CVD may differ from that of ALA. These results are strengthened by results seen in other prospective studies such as the Multiple Risk Factor Intervention Trial, which showed a significant reduction in CHD fatality across quintiles of ALA intake; 0.56 g/day difference in ALA intake resulted in a 42% reduction in fatal CHD (20). Conversely, fewer epidemiological studies have looked specifically at lignan intake and CHD. The Kuopio Ischaemic Heart Disease Risk Factor Study, a 7.7-year follow-up study on men who suffered a CHD found that plasma enterolactone levels were significantly lower in cases versus control (21). A Dutch prospective study, however, showed no association between plasma enterolignan levels and the risk of non-fatal myocardial infarction (22). Conflicting evidence can be related to several factors including methods of lignan analysis, small range of plasma lignan levels, and the food sources of the lignans. Nonetheless, these epidemiological studies suggest that flaxseed has components that may be potentially effective in reducing the risk of CHD.

Mechanisms of Action

As mentioned previously, flaxseed has consistently been shown to reduce atherosclerosis in two animal models; however, there is a disagreement in its effect on blood lipids depending on the model and therefore other mechanisms may also be responsible for the antiatherogenic effect of flaxseed.

Other mechanisms that have been suggested for flaxseed's protective effect against CVD are summarized in Table 2 and include: (a) Reducing oxidative stress, which is associated with the development of atherosclerosis: Lignans have been shown to have anti-oxidant activities in *in vitro* studies (23); however, flaxseed intake did not ameliorate oxidative stress in clinical trials (24); (b) Anti-inflammatory action: n-3 fatty acids have demonstrated anti-inflammatory effects (7) and infectious disease and inflammation contribute to the development of atherosclerosis (25). Flaxseed supplementation has been shown to reduce markers of inflammation in mice [e.g., interleukin (IL)-3, vascular cell adhesion molecule-1 (VCAM-1)] (26) and ALA supplementation from flaxseed oil has been shown to reduce inflammatory markers [e.g., C-reactive peptide (CRP), serum amyloid A, IL-6, and soluble VCAM-1] in dyslipidemic patients (27). Flax lignan complex (dose providing 500 mg SDG/day for six weeks) effect on inflammation was studied in healthy postmenopausal women and was found to reduce plasma levels of CRP but had no effect on other markers including IL-6 and sVCAM-1 (28). This indicates that lignans may have a small anti-inflammatory effect; however, more studies are needed. (c) Endothelial effect: Animal studies have shown that flaxseed can protect against the dysfunctional contraction and relaxation of the aorta that accompanies high dietary cholesterol-induced atherosclerosis (29). Clinical studies have shown that flaxseed oil supplementation in obese adults increased systemic arterial compliance, a marker of endothelial function (30). On

the other hand, dietary lignan complex (500 mg of SDG) in postmenopausal women did not result in any benefit in endothelial function (31). These results indicate that it may be the oil component that plays a role in flaxseed's endothelial effect. (d) Antiarrhythmic effect: n-3 fatty acids have been shown using rat, nonhuman primate, and dog models to have antiarrhythmic properties (7). Studies comparing the effect of ALA to DHA have shown that ALA can reduce the heart rate to the same extent as DHA although it is a delayed effect. An intervention study conducted in humans was unable to confirm the antiarrhythmic effect of ALA. Prospective studies have, however, suggested a link between ALA intake and decreased risk for abnormally prolonged repolarization of the heart muscle (32), between ALA content of the adipose tissue and improved heart rate variability score indicative of reduced arrhythmia risk (33). Further research is needed to determine the effect of ALA on cardiac rhythm. (e) Platelet aggregation: In the rabbit model, flaxseed oil treatment inhibited thrombin and fibrinogen-induced platelet aggregation (34). Furthermore in apolipoprotein E^{-/-} LDLR^{-/-} mice, an n-6/n-3 ratio of 0.29:8 provided by flaxseed oil and safflower oil caused a dose-dependent antithrombotic effect (35). Results of these animal studies have not been consistently confirmed in human studies. One small study showed that 40 g/day of flaxseed oil for 23 days reduced platelet aggregation in healthy men (36); however, a larger study showed no anti-platelet effect of flaxseed oil (37). Two clinical studies looked at the effect of milled flaxseed feeding and platelet aggregation and both have shown a beneficial effect (38,39). More research is needed to elucidate the mechanisms responsible for these effects.

Breast Cancer

Animal Studies

Because of the potential hormonal effects of flaxseed and its lignans, more work has been done on their effect on hormone-related cancer such as breast and prostate cancer than the other types of cancer, although much of the work has been conducted using animal models. As previously reviewed (2,3,40), flaxseed (5%) fed before (preinitiation stage) or after carcinogen administration (promotion stage) in rats reduced the incidence and number of mammary tumors compared with the control. When flaxseed was fed nine weeks after carcinogen treatment (progression stage), tumors regressed by >50%. Similar effects were observed when SDG, its enterolactone metabolite, or flaxseed oil was fed, indicating that both the lignans and the flaxseed oil play a role in the flaxseed effect. Flaxseed at 10% level also reduced the tumor growth and metastasis incidence in athymic mice with human estrogen receptor negative (ER-) breast cancer, particularly in the lung and lymph node. SDG and flaxseed oil at levels present in 10% flaxseed similarly reduced the metastasis incidence, demonstrating that the lignan and oil components of flaxseed contribute to the antimetastatic effect of flaxseed (41). Flaxseed can reduce metastasis even after tumor is excised, but is more effective in reducing tumor recurrence when the excised tumor is still small (42). In ovariectomized (OVX) athymic mice with established human ER+ breast tumors (MCF-7) at low circulating estrogen level to simulate postmenopausal situation, 10%

flaxseed diet regressed the tumor size to a greater extent than the control and this effect was the same as that of pure SDG at levels equivalent to that in the 10% flaxseed diet (43). However, the effect of the SDG-rich flaxseed hull fraction equivalent to the amounts present in 10% flaxseed did not reduce the tumor growth to the same extent as the pure SDG, indicating that the hull fraction may need a higher level of intake to produce the same effect (43). The SDG is more effective at regressing the tumor growth than the flaxseed oil (44). Flaxseed, SDG, and flaxseed oil did not interfere with, but rather increased the effectiveness of tamoxifen, a primary breast cancer drug, in reducing human tumor growth in mice, at both low and high levels of circulating estrogen (45,46). Although SDG and flaxseed oil were responsible for the flaxseed effect, flaxseed oil was more effective than the SDG when fed in combination with tamoxifen treatment (46).

Clinical Trial

To test whether the effect seen in the animal models can be reproduced in humans, a randomized, double-blind, placebo-controlled clinical trial was conducted in postmenopausal women with newly diagnosed breast cancer (47). The patients consumed 25 g flaxseed in muffin formulation or placebo muffin daily for a mean duration of 32 and 39 days, respectively. Tumor biopsies taken before and after the feeding periods showed 34% lower rate of cell proliferation, 71% lower expression of c-erbB2 (neu, HER2), and 31% increase in apoptosis in the flaxseed group while no significant change was observed in the placebo group. These changes, which suggest slower tumor growth and better prognosis in the flaxseed group, were significantly correlated with the urinary lignan excretion and the amount of flaxseed consumed, in agreement with observations in the animal models. Overall, therefore, the animal studies and this clinical trial are in agreement that flaxseed and its lignans and oil components do not promote tumor growth and may even be protective against breast cancer.

Epidemiological Studies

Breast cancer risk has not been related to the intake of flaxseed in epidemiological studies but has been related to the intake of lignans or ALA. A recent meta-analysis that included 6 cohort, 6 nested case control, and 10 case-control studies showed no association between plant lignan intake and breast cancer risk in all women but a significant 15% reduction in risk was observed in postmenopausal but not in premenopausal women (48). In contrast, blood enterolactone level was not associated with breast cancer regardless of menopausal status. The significant effect of plant lignan intake in postmenopausal women indicates that the lignans may be more effective only at low estrogen level but the reason for this is still not very clear. In a recent prospective study of 51,823 women with average 8.3 years follow-up, a significant inverse association between lignan intake and breast cancer risk was observed especially among postmenopausal hormone users but there was no heterogeneity across ER/progesterone receptor (PR) subtypes (49). Others have shown, however, that the inverse association between plasma enterolactone and breast cancer risk was

significantly different between ER α and ER β tumors and most evident in ER α but not in ER β tumors (50).

Epidemiological studies on the relationship between ALA and breast cancer are conflicting (3). While significant relationship between high levels of ALA in the adipose tissue of breast cancer patients and the lower incidence of breast cancer metastasis has been observed, no tendency to decrease breast cancer risk was associated with increased serum or erythrocyte ALA levels. In a recent study of 56,007 French women with eight years follow-up, breast cancer risk was inversely associated with the intake of ALA from fruits and vegetables but was positively related to ALA intake from nut mixes and processed foods (51). ALA intake was also positively associated in women in the highest quintile of dietary vitamin E, indicating the need to consider not only food sources but also interaction of the fatty acids with anti-oxidants when determining the association of fatty acids with breast cancer.

Mechanisms of Action

The mechanisms of flaxseed effect on breast cancer have been attributed to the activities of its lignans and ALA-rich oil components. Regarding the lignans, suggested mechanisms as previously reviewed include the following (3,11,40,52): (a) Lignans may interfere with the binding of endogenous estrogen to ER α and ER β thus altering its action. They have been shown to bind weakly to ER α and ER β . (b) They can reduce the availability of estrogens by inhibiting the activities of enzymes involved in the synthesis and regulation of estrogen synthesis: aromatase, 17-hydroxysteroid dehydrogenase, and 5 α -reductase. However, while serum estradiol was reduced after the intake of 5 g or 10 g flaxseed, a study showed that consumption of ground flaxseed at 7.5 g/day for six weeks and then 15 g/day for six weeks did not significantly reduce estradiol, estrone, and testosterone in postmenopausal women although it significantly reduced estrone in overweight/obese women (53). (c) They can also stimulate the production of sex hormone-binding globulin that binds estrogen and testosterone and thus reduce their free concentration and availability in the plasma; however, results on this are conflicting with some showing this effect while others do not. (d) They can alter the metabolism of estrogen that leads to the production of 2-hydroxyestrone (2OHE1) and 16-hydroxyestrone (16OHE1). Since 2OHE1 has low biological (estrogenic) activity while 16OHE1 has estrogenic activity, an increase in 2OHE1 to 16OHE1 has been suggested to be associated with reduced breast cancer risk. Flaxseed (10–25 g/day) has been shown to increase the ratio of 2OHE1 to 16OHE1 in pre- and postmenopausal women indicating a protective effect. (e) They may modify estrogen and growth factor action through several mechanistic pathways. Flaxseed and its lignans have been shown to reduce cell proliferation, increase apoptosis, decrease angiogenesis, and the expressions of ER α , ER β , pS2, Bcl2, cyclin D1, insulin-like growth factor-1 (IGF-1), IGF-I receptor (IGF-IR), human epidermal growth factor receptor 2 (HER2), epidermal growth factor receptor (EGFR), vascular endothelial growth factor (VEGF), mitogen-activated protein kinase (MAPK), and Akt, indicating that their effects include the downregulation of the ER and growth factor-mediated signaling pathways (43–46,54). (f) Nonhormone-related mechanisms may also be

involved. In vitro studies using various test models have shown that lignans (10–100 μ M) have anti-oxidant activities (23,55). However, feeding flaxseed to postmenopausal women did not show significant changes in various anti-oxidant biomarkers in the human plasma (24), although flaxseed and SDG reduced oxidative stress in the hypercholesterolemic rabbits (10).

Regarding ALA-rich oil, its mechanisms have been related in part to the inhibition of the formation of prostaglandin E₂ (PGE₂), leukotriene B₄ (LTB₄), and LTC₄ from the n-6 fatty acids, which have been shown to directly stimulate the growth of malignant cells in addition to their effects on humoral and cell-mediated immunity. Other suggested mechanisms include alteration of the lipid composition of tumor cell membranes, hence affecting membrane fluidity and growth factor expression and signal transduction that influence tumor growth. It can also form cytotoxic peroxidation products (56).

Prostate Cancer

Animal Studies

The role of lignans on prostate cancer has been reviewed (3,11). Flaxseed-derived lignans reduced the growth in vitro of LNCaP, DU-145, and PC-3 prostate cancer cell lines. Flaxseed diet inhibited the prostate tumor growth and development in the transgenic adenocarcinoma mouse prostate model (57). A plant lignan hydroxymatairesinol, which like SDG can be metabolized to the enterolignans, increased the proportion of nongrowing tumors, decreased cell proliferation, and increased cell apoptotic index in nude mice transplanted with LNCaP human prostate cancer cells compared with control (58).

Clinical Trials

In a pilot study, men scheduled for prostatectomy surgery consumed a low-fat diet supplemented with 30 g ground flaxseed/day (59). After an average 34 days, the cell proliferation index was significantly lower and apoptotic index was higher when compared with historical matched controls. A follow-up study determined the effect on prostate cancer patients of low-fat diet, and 30 g flaxseed diet, alone and in combination, for an average 30 days (60). A significant reduction in tumor cell proliferation index in the flaxseed arms but no effect on apoptotic index and other biomarkers were observed. These clinical trials support the hypothesis that flaxseed maybe protective against prostate cancer.

Epidemiological Studies

In contrast, some epidemiological studies (meta-analysis) showed an increased risk of prostate cancer associated with high intake or blood level of ALA, with the association stronger in case-control than in prospective studies (61). In one systematic review and meta-analysis of eight case-control and eight prospective studies, high ALA intake or tissue concentration was weakly positively associated with prostate cancer risk (62). However, the authors qualified this conclusion because of significant heterogeneity across studies and evidence of publication bias. Furthermore, food sources of ALA in these studies were predominantly meat, dairy products, and salad dressings and not flaxseed. A more recent meta-analysis of five

prospective studies support a weak protective association between prostate cancer risk and ALA intake (63). Those that consume >1.5 g ALA/day has lower prostate cancer risk than those who consumed <1.5 g ALA/day. Obviously, the conflicting effect of ALA on prostate cancer needs to be resolved. Epidemiological studies have not shown a significant association between plasma enterolactone and prostate cancer (64).

Mechanisms of Action

Because flaxseed has both the ALA and lignans and yet clinical trials showed protective effect of flaxseed against prostate cancer, it is possible that any potential adverse effect caused by ALA may have been modified by the lignans in flaxseed where they are together. The mechanism of any ALA effect on prostate cancer is not clear. In contrast, in in vitro studies, it was shown that the inhibitory effect of the lignan enterolactone on the growth of PC-3 prostate cancer cells is in part through inhibition of IGF-1/IGF-IR signaling; it inhibited the activation of IGF-IR and its downstream AKT and MAPK and their phosphorylation (65). Cyclin D1 expression was also downregulated. Some of the mechanisms mentioned under breast cancer may likewise be possible in prostate cancer, it being a hormone-sensitive cancer.

Colon Cancer

The effect of flaxseed and its lignans and oil on colon cancer is conflicting. In vitro studies showed that enterolactone and enterodiol can reduce the cell proliferation and induce cell-cycle arrest of colon cancer cells (11). In carcinogen-treated rats, aberrant crypts (precursors of adenoma and colon cancer) were reduced by 2.5% to 10% flaxseed diet and purified SDG (66). Lower number and incidence of colon tumors with flaxseed oil feeding have also been observed (67). However, 5% flaxseed (68) or pure secoisolariciresinol or matairesinol at 0.02% in diet (69) did not reduce tumor growth in Apc Min mouse, a mice model for adenomatous polyposis coli multiple intestinal neoplasia, although another study using the same mice model showed reduced colon tumorigenesis (70). Any discrepancy was thought to be related in part to the fact that enterolignans are formed from the plant lignans in the colon, while in the APC Min mouse the tumors are formed primarily in the small intestine.

Regarding epidemiological studies, case-control studies showed an inverse association between colorectal cancer risk and plasma lignan levels (71) or lignan intake (72). However, a prospective Dutch study of 35,000 subjects with average 7.5 years follow-up did not support the association of high plasma enterolignan concentration with a reduction in colorectal cancer after adjustment for colorectal cancer risk factors (73).

The effect of flaxseed or its oil on colon cancer development has been attributed to the increase in the n-3 fatty acids and reduction in cyclooxygenase 1 and 2 (COX1 and COX2) levels in the serum and colon tissues (67,70) and reduction in IGF-1 signaling (74).

Bone Health

Mammalian lignans and n-3 fatty acids have been shown to exert direct effects on bone cells in in vitro studies through modulation of cell viability, DNA content, and

biomarkers of bone formation (75,76). Flaxseed is a rich source of both components indicating its potential to improve bone health.

Animal Studies

In animal models, dietary flaxseed has transient effect on bone composition and strength. For example, female rats fed 5% or 10% flaxseed or 6.2% defatted flaxseed resulted in decreased plasma alkaline phosphatase, an indicator of bone formation (77); this also indicates that the flaxseed effect may be due to the defatted portion (i.e., lignan, dietary fiber). Dietary lignan, at levels present in 5% and 10% flaxseed, fed during suckling alone or through to different developmental stages (i.e., adolescence, adulthood) increased femur strength at adolescence without a change in bone mineral content (BMC) (78). The effect was no longer seen at adulthood indicating that female rat bone is more sensitive to lignans during early life when endogenous levels of sex hormones are low (i.e., adolescence). In male rats, flaxseed, but not SDG, fed through to adolescence reduced biomechanical strength but again this was not seen in adulthood (79). These studies indicate that flaxseed and SDG may have gender-specific effects on bone, which do not last into adulthood.

The effect of flaxseed feeding was studied in OVX rodents, which models the postmenopausal, osteoporotic situation. A 10% flaxseed diet fed for 12 weeks resulted in no change in bone strength or composition (80) but fed for 25 weeks, increased biomarkers of bone strength (81). In one study, no benefit of treatment with enterolactone or enterodiol was observed in the bone of OVX mice with human breast cancer (82). However, flaxseed feeding enhanced the effectiveness of low-dose estrogen therapy on bone properties indicating that flaxseed may provide a benefit for patients in treating the bone loss that accompanies menopause (80). Evidently, controversy remains in the effect of flaxseed and its components on bone health in animal models and a further study of functional measures of bone strength are needed.

Clinical Trials

Regarding clinical studies, three randomized, double-blinded, placebo-controlled trials [(two short term, 3–4 months) (83,84) and one long term (12 months) (85)] in healthy postmenopausal women showed no significant effect of dietary flaxseed between baseline to end of study and placebo versus treatment on bone mineral density (BMD) and biomarkers of bone metabolism. A randomized placebo-controlled trial conducted to determine the effect of flaxseed lignan complex supplementation (543 mg lignan complex/day in a tablet form, 32.9% SDG) during an exercise program on bone health in men and women older than 50 years showed no significant changes in BMD and BMC (86). In a double-blinded crossover trial, a high ALA diet (LA/ALA = 1.6/1) provided by flaxseed oil and walnut oil fed for six weeks to hypercholesterolemic and overweight men and women significantly reduced serum N-telopeptides of type 1 collagen, tumor necrosis factor- α (TNF- α) (proinflammatory cytokine and osteoclastogenic factor) compared with a low ALA diet (LA/ALA = 9.5/1) without affecting bone-specific alkaline phosphatase (87). No differences were seen in BMD between groups but this may be attributed to short study duration. These results

suggest that ALA-rich flaxseed oil may be beneficial in bone health by decreasing bone breakdown through an attenuation of osteoclastic activity.

Epidemiological Studies

Regarding epidemiological studies, greater urinary enterolactone levels were correlated with higher BMD in Korean postmenopausal women with existing osteoporosis (88). However, in a study of healthy Dutch postmenopausal women with low ($\leq 0.5\%$) or high ($\geq 2.5\%$) rates of cortical bone loss at the radius, greater urinary enterolactone level was correlated with greater rates of bone loss (89). There are many possibilities for the discrepancies in these results including variations in subject populations (osteoporotic vs. healthy) and methods of enterolactone analyses. ALA's role in bone loss prevention was seen in a study showing that higher LA to ALA ratio was associated with a lower hip BMD in healthy older men, menopausal women not using hormone replacement therapy (HRT), and postmenopausal women using HRT (90).

Although clinical studies showed that flaxseed and its lignan component may have little effect in the prevention of osteoporosis, it is important to note that no adverse effects were seen. ALA may be beneficial in the prevention of bone loss; however, further studies of longer duration are necessary to determine whether this effect will translate into increased BMD and bone strength.

Menopausal Symptoms

Since flaxseed is one of the richest dietary sources of the phytoestrogen SDG, the precursor of enterodiol and enterolactone that may mimic the activity of estrogen, studies have assessed its potential to attenuate symptoms that come with the loss of endogenous estrogen production of menopause. Many menopausal women suffer from hot flashes, night sweats, and vaginal dryness and although HRT has been proven to prevent and relieve these symptoms, it is associated with an increased risk of specific diseases such as CVD and breast cancer.

A randomized crossover clinical study compared the effectiveness of flaxseed supplementation to HRT and showed that flaxseed feeding for two months attenuated symptoms as effectively as two months of HRT (91). However, in a randomized, double-blind, wheat germ placebo-controlled clinical trial of 190 women, both flaxseed (40 g/day) and the wheat germ placebo for one year significantly reduced severity scores of menopausal symptoms from baseline but there was no difference between these groups (85). No significant effect of flaxseed was also observed in another randomized placebo-controlled trial (92) indicating the need for placebo when conducting studies on menopausal symptoms. In one study, flaxseed supplementation to postmenopausal women suffering from hot flashes showed a greater than 50% reduction in hot flush scores compared with baseline (93). There was no placebo control group in this study but they concluded that the reduction in hot flush activity was greater than what would have been seen with a placebo. Other clinical studies that have been reviewed (3) showed varied results with some showing no effect and some showing benefit in only specific symptoms (hot flashes and vaginal dryness). Flaxseed supplementation showed no adverse

effect; however, in one study where soy was also used as an intervention, an increase in vaginal cytology maturation index was seen (94).

Other Potential Health Benefits

Several animal models have shown that flaxseed and in particular SDG can reduce the development of diabetes and this effect was associated with the ability of SDG to reduce oxidative stress (95). Flaxseed decreased plasma glucose and insulin levels in hypercholesterolemic women (91). In a randomized placebo-controlled crossover trial of type 2 diabetics with hypercholesterolemia, supplementation with flaxseed-derived lignan capsules (360 mg/day) for 12 weeks improved glycemic control (96) and also modulated the CRP levels in type 2 diabetics although it was observed more in women and not in men (97). Daily consumption of 5 g flaxseed gum (dietary fiber) by type 2 diabetics has also been shown to reduce blood glucose response as well as total and LDL cholesterol (98). However, flaxseed oil (10 g/day) has no effect on glycemic control in type 2 diabetes (99).

Flaxseed, cold pressed flax meal or its isolated dietary fiber (gum) has been shown to improve laxation or reduce constipation, a well-known effect of high fiber diet (100,101). Other suggested beneficial effects of flaxseed include treatment improvements in kidney disease (3); however, studies in this area are still very limited.

SAFETY

The presence of cyanogenic glycosides is a concern but considering that adults can detoxify 30 to 100 mg of cyanide/day, one needs to consume large amounts of flaxseed to show cyanide toxicity (10). An intake of >10 tablespoons/day (~100 g) of raw milled flaxseed is estimated to raise the cyanogen levels above 50 to 60 mg. Heat treatment destroys cyanogens in flaxseed and the amounts present in baked products or cereals may not pose problems. Cadmium is also present in flaxseed but the risk associated with it has been suggested to be less than that from rice or wheat. However, flaxseed with very high levels of cadmium may have estrogenic effect and may be a concern when consumed during pregnancy and lactation. Flaxseed contains vitamin B6 antagonist (linatine) but this has not been considered a problem because the diet normally contains sufficient amounts of vitamin B6. Although very rare, some individuals may have anaphylactic or allergic reaction to flaxseed so one has to test for it before consuming large amounts of flaxseed. Gastrointestinal discomfort associated with intake of large amounts of dietary fiber is often reported with flaxseed intake.

Recently, a meta-analysis of 174 randomized controlled trials determined the side effects (broadly categorized as gynecological, gastrointestinal musculoskeletal, neurological) of phytoestrogens including the lignans and isoflavones although more on the latter (102). It was concluded that the phytoestrogens caused moderately elevated rates of gastrointestinal side effects but did not significantly increase rates of vaginal bleeding, endometrial hyperplasia, endometrial cancer, and breast cancer and have generally safe side effect profile.

Safety of flaxseed interaction with drugs has to be taken into consideration when consuming flaxseed or its lignan or oil components (103). For example, flaxseed decreases platelet aggregation and increases bleeding time; therefore it may increase the risk of bleeding when taken with anti-platelet or anti-coagulant drugs. Because of the hormonal action of lignans, it is surmised that flaxseed intake may enhance tumor growth and interfere with the action of hormone-related treatments, for example, tamoxifen, HRT. However, as mentioned earlier, most animal studies and clinical trials have shown that flaxseed, or its lignans or oil do not promote tumor growth and does not interfere but rather enhance the effectiveness of tamoxifen. Furthermore, animal studies have shown that flaxseed combined with low-dose estrogen therapy lead to a greater BMD and peak load at the tibia in OVX rats. Further studies need to be conducted to assess the potential harmful or beneficial interactions between flaxseed and other hormone-related therapies.

REGULATORY STATUS

Every country has its own regulations for the use of flaxseed. There is currently no regulation regarding the level of flaxseed that can be added to foods but there is no objection to the use of flaxseed at 8% level in baked products or at 4% in dry cereal in Canada, and at 12% level in the United States. Recently, however, the U.S. Food and Drug Administration (FDA) gave a no objection decision to the request of Flax 2015 and Flax Council of Canada to consider whole and milled flaxseed as GRAS (generally recognized as safe) (104). GRAS is an FDA designation that means the substance is considered safe by experts and therefore is exempted from the Federal Food Drug and Cosmetic Act food tolerance requirements. The decision was based on observations that (a) flaxseed products have long history of use and regarded as safe and nutritious, (b) animal and human research has confirmed its safety, and (c) the composition and purity of whole and milled flaxseed have been adequately characterized to assure a wholesome food grade product. The addition of flaxseed to conventional foods is considered safe and limited only by current Good Manufacturing Practices. In Canada, food manufacturers are allowed to state in the Nutrition facts label the n-3 fatty acid (ALA) content per serving. In the United States, the Nutrition label can include the percent of the Daily Value for ALA per serving.

CONCLUSION

Flaxseed is an ancient crop that in recent years increased in popularity as food because of its suggested health benefits. The benefits have been attributed to its exceptionally high levels of n-3 fatty acid (ALA)-rich oil, phytoestrogen lignans especially SDG, and dietary fiber, components that have also been isolated as fractions or extracts to be used as dietary supplements. Whole flaxseed and the lignan have been shown to improve plasma TC and LDL-C with no effect on plasma HDL-C and TG particularly in hyperlipidemic individuals. The ALA-rich flaxseed oil has little effect on blood lipids but has also been linked to reduced

risk of CVD events perhaps through lipid-lowering independent mechanisms. There is evidence suggesting that flaxseed and its SDG or oil components have anti-oxidant, anti-inflammatory, antiarrhythmic, anti-platelet aggregation, and good endothelial function effects, which can help reduce CVD risk, but more research is needed to further establish mechanisms. Extensive animal studies are consistent in showing that flaxseed can reduce breast tumor development at various stages of carcinogenesis including preinitiation, promotion, progression, and metastasis. A clinical trial with breast cancer patients agreed with the observation that flaxseed does not promote but rather reduces breast tumor growth. However, this needs further confirmation in trials with large number of subjects. Both the lignan and the oil appear to contribute to the breast cancer protective effect involving both hormone and nonhormone-related mechanisms. Limited evidence suggests that flaxseed and lignans are protective against prostate cancer but the role of ALA is less clear. There is conflicting evidence for the protective role of flaxseed on colon cancer. Flaxseed does not seem to have strong effect, positive or negative, on bone health; if any, flaxseed oil may have a better effect. However, animal studies suggest that flaxseed may enhance the effectiveness of low-dose estrogen therapy. There is little effect of flaxseed consumption in reducing menopausal symptoms and those that have been observed may be attributed to a placebo effect. Potential health benefits of flaxseed and SDG in reducing diabetes risk have been suggested in some animal and human studies. As an excellent source of dietary fiber, flaxseed is well known to exert a laxative effect.

Whole or milled flaxseed is considered safe for consumption; hence the U.S. FDA has indicated no objection in considering flaxseed as GRAS. ALA is an essential PUFA with the Adequate Intake established by the National Academies' Institute of Medicine at 1.6 g/day for adult males and 1.1 g/day for adult females. This can be met with the daily intake of less than 10 g flaxseed or 4 g flaxseed oil. In clinical studies, the daily consumption levels tested for reduction in disease risks ranged from 10 to 50 g flaxseed, 1 to 40 g flaxseed oil, and 50 to 600 mg flaxseed lignan. However, more research is needed to find the optimal dose for these components to exert the desired health benefit.

Folate

Pamela Bagley and Barry Shane

INTRODUCTION

Folate is a dietary essential B-complex vitamin required for human health. It functions as a cofactor in the synthesis of nucleotides required for DNA synthesis and in amino acid metabolism. The classic symptom of folate deficiency is megaloblastic (large cell) anemia, which is a reflection of defective DNA synthesis. Poor folate status is also a risk factor for cancer. The finding that periconceptional folate supplementation greatly reduces the incidence of birth defects in humans has led to fortification of the food supply with folic acid in the United States and other countries.

STRUCTURE AND CHEMISTRY

Folate is a generic term for a family of chemically and functionally related compounds based on the folic acid structure (Fig. 1). Folic acid (molecular weight 441.4), also known as pteroylmonoglutamate, is an oxidized, synthetic form of the vitamin and consists of a pterin (2-amino-4-hydroxy-pteridine) ring linked to para-aminobenzoic acid, which is conjugated to a molecule of L-glutamic acid. Folic acid is reduced within the cell to the metabolically active 5,6,7,8-tetrahydrofolate form. Folates in tissues act as donors and acceptors of one-carbon units in metabolic reactions known as one-carbon metabolism. These one-carbon units can be at the oxidation level of methanol (5-methyl-tetrahydrofolate), formaldehyde (5,10-methylene-tetrahydrofolate), or formate (5- or 10-formyl-tetrahydrofolate or 5,10-methenyl-tetrahydrofolate). The predominant coenzyme forms are listed in Table 1.

Figure 1 Structure of folic acid (pteroylglutamate). One-carbon substituents can be at the N-5 and/or N-10 positions of the reduced tetrahydrofolate molecule.

Table 1 Metabolically Active Forms of Folate^a

Unsubstituted folates	
7,8-Dihydrofolate (reduced at positions 7 and 8)	
5,6,7,8-Tetrahydrofolate	
Substituted folates	One-carbon group
5-Methyl-tetrahydrofolate	-CH ₃
5-Formyl-tetrahydrofolate (folinic acid, leucovorin)	-CHO
5-Formimino-tetrahydrofolic acid	-CHNH
10-Formyl-tetrahydrofolate	-CHO
5,10-Methylene-tetrahydrofolate	-CH ₂ -
5,10-Methenyl-tetrahydrofolate	-CH-

^aActive forms are polyglutamate derivatives.

Practically all tissue folates are polyglutamate forms in which the glutamate tail is extended via an unusual peptide bond via the γ -carboxyl of glutamate. Glutamate chain lengths can vary from approximately 4 to 10 in human tissues. Metabolism of folates to polyglutamate forms is required for their biological activity, as the polyglutamate forms are much more effective substrates for folate-dependent enzymes than are the monoglutamate derivatives, which are the transport forms of the vitamin (1). Conversion of folates to polyglutamates of chain length greater than three or more is also required for effective retention of folate by tissues (2), and allows tissues to maintain much higher folate levels than in plasma.

BIOCHEMISTRY AND FUNCTIONS

Folate coenzymes are involved in three major inter-related metabolic cycles in the cytosol of cells. These cycles are required for the synthesis of thymidylate and purines, precursors for DNA and RNA synthesis, and for the synthesis of methionine from homocysteine and the interconversion of serine and glycine (Fig. 2).

5,10-Methylene-tetrahydrofolate plays a central role in these cycles as it can be used directly for thymidylate synthesis or it can be reduced to 5-methyl-tetrahydrofolate in the methionine synthesis cycle or can be oxidized to 10-formyl-tetrahydrofolate to be used in purine synthesis. Although the enzymes involved in these synthetic cycles are normally located in the cytosol, during the S phase of the cell cycle the enzymes involved in thymidylate synthesis translocate to the nucleus, which also contains a folate pool (3). Mammalian cells also contain a large, separate mitochondrial folate pool that is involved in serine and choline metabolism and in the provision of one-carbon precursors for cytosolic one-carbon metabolism (4,5).

Figure 2 The major metabolic cycles of folate-dependent one-carbon metabolism in the cytoplasm of cells. The cycles use reduced tetrahydrofolate (THF) polyglutamates as substrates. **Abbreviations:** SHMT, serine hydroxymethyltransferase; MTHFR, methylene-tetrahydrofolate reductase; MS, methionine synthase; TS, thymidylate synthase; DHFR, dihydrofolate reductase; MTHFD, methylene-tetrahydrofolate dehydrogenase; CYH, methenyl-tetrahydrofolate cyclohydrolase; GART, GAR formyltransferase; AICART, AICAR formyltransferase; dUMP, deoxyuridine monophosphate; dTMP, deoxythymidine monophosphate; FAICAR, formyl-aminoimidazole carboxamide ribonucleotide; AICAR, aminoimidazole carboxamide ribonucleotide; GAR, glycylamide ribonucleotide; FGAR, formyl-glycylamide ribonucleotide; DHF, dihydrofolate; NADP, nicotinamide adenine dinucleotide phosphate; B₁₂, vitamin B₁₂ (cobalamin).

Serine–Glycine Interconversion

Serine is the major provider of one-carbon units for folate-dependent one-carbon metabolism (1). It donates its β -carbon to tetrahydrofolate to generate glycine and 5,10-methylene-tetrahydrofolate. The reaction, which is catalyzed by the pyridoxal phosphate (PLP)-dependent enzyme serine hydroxymethyltransferase (SHMT), is at near equilibrium and can be easily reversed. Mammalian tissues contain two distinct isozymes of SHMT, one cytosolic and one mitochondrial, encoded by different genes (6). The mitochondrial isozyme, which is expressed in all tissues, may be responsible for the generation of the majority of one-carbon units required for cytosolic one-carbon metabolism (7). 5,10-Methylene-tetrahydrofolate generated via the mitochondrial SHMT reaction can be oxidized to 10-formyl-tetrahydrofolate and then hydrolyzed to formate. The formate produced exits the mitochondria and the one carbon is reincorporated into the cytosolic one-carbon pool as 10-formyl-tetrahydrofolate. 10-Formyl-tetrahydrofolate can be reduced to 5,10-methylene-tetrahydrofolate in the cytosol via the action of a reversible trifunctional C1 synthase enzyme. The tissue distribution of the cytosolic isozyme of SHMT is more limited than the mitochondrial enzyme. The cytosolic isozyme is highly expressed in the liver and kidney and in rapidly replicating cells. A major role of the hepatic cytosolic SHMT enzyme may be to synthesize serine from glycine for use in gluconeogenesis. Mammalian cell mutants that lack mitochondrial SHMT but express cytosolic SHMT are glycine auxotrophs (8).

Nucleotide Synthesis

Folate is required for the synthesis of thymidylate, a nucleotide required specifically for DNA synthesis and repair. Thymidylate synthase catalyzes the transfer of the one-carbon group from 5,10-methylene-tetrahydrofolate to the 5'-position of deoxyuridine monophosphate (dUMP) and its reduction to a methyl group to generate deoxythymidine monophosphate (dTMP). The folate

molecule also provides the reducing component in this reaction and the tetrahydrofolate is oxidized to dihydrofolate. The dihydrofolate generated has to be reduced back to tetrahydrofolate before it can be reutilized in one-carbon metabolism in a reaction catalyzed by dihydrofolate reductase (DHFR). Thymidylate synthetase activity is primarily expressed in replicating cells during the S phase of the cell cycle and is highest in fast growing cells. Consequently, drugs targeted to DHFR, such as methotrexate, have proven to be effective chemotherapeutic agents as they are selective inhibitors of rapidly growing cells (9,10). Some of the cytosolic folate enzymes involved in provision of thymidylate are sumoylated and translocate to the nucleus during the S phase of the cell cycle (3). These include thymidylate synthase, DHFR, and cytosolic SHMT. In addition, a variant form of mitochondrial SHMT, which is expressed from a second promoter on the mitochondrial SHMT gene and contains a different exon 1 lacking a mitochondrial leader sequence, is also found in the cytosol of cells and also translocates to the nucleus during the S phase of the cell cycle (11).

Cytosolic folate coenzymes are also used in two steps of de novo purine biosynthesis. The C-8 and C-2 positions of the purine ring are derived from 10-formyl-tetrahydrofolate in reactions catalyzed by glycylamide ribonucleotide (GAR) transformylase and 5-amino-4-imidazolecarboxamide ribonucleotide (AICAR) transformylase. The enzymes involved in de novo purine are multifunctional and form a complex in the cytosol called the purinosome (12). This complex remains in the cytosol during the S phase of the cell cycle.

Methionine Synthesis

The methylation of homocysteine to produce methionine uses 5-methyl-tetrahydrofolate as the methyl donor in a reaction catalyzed by methionine synthase, one of only two vitamin B₁₂-dependent enzymes in mammals (Figs. 2 and 3) (13). 5-Methyl-tetrahydrofolate is generated from 5,10-methylene-tetrahydrofolate in a reaction

Figure 3 The folate-dependent methionine synthesis cycle and the transmethylation cycle. Abbreviations: THF, tetrahydrofolate; FAD, flavin adenine dinucleotide; PLP, pyridoxal phosphate; B₁₂, vitamin B₁₂; AdoMet, adenosylmethionine; AdoHcy, adenosylhomocysteine; SHMT, serine hydroxymethyltransferase; MTHFR, methylene-tetrahydrofolate reductase; MS, methionine synthase; MATII, methionine adenosyltransferase; SAHH, AdoHcy hydrolase.

catalyzed by the flavoprotein methylenetetrahydrofolate reductase (MTHFR). Methionine can be metabolized to S-adenosylmethionine, which acts as the methyl donor in many reactions, including the methylation of DNA, histones and other proteins, neurotransmitters and phospholipids, and the synthesis of creatine. These methylation reactions play important roles in development, gene expression, and genomic stability. S-Adenosylhomocysteine, the product of methylation reactions, is a potent inhibitor of many methyltransferases and is catabolized by hydrolysis to adenosine and homocysteine. In liver and kidney, homocysteine can be further metabolized to cysteine via the transsulfuration pathway utilizing the PLP-dependent enzymes cystathionine- β -synthase (CBS) and cystathioninase. In most other tissues, homocysteine is exported to the circulation or is reconverted back to methionine via the folate-dependent methionine synthase reaction.

Homocysteine can also be remethylated to methionine by cytosolic betaine homocysteine methyltransferase (BHMT), a folate-independent enzyme that is expressed in high levels in liver and in some species, including humans, in kidney (14). Betaine (trimethylglycine) is derived from mitochondrial oxidation of choline. Dimethylglycine, the product of the BHMT reaction, is oxidized in the mitochondria to sarcosine (methylglycine) and then to glycine by the folate-dependent flavoproteins dimethylglycine dehydrogenase and sarcosine dehydrogenase. Each oxidation results in the formation of a molecule of 5,10-methylene-tetrahydrofolate from tetrahydrofolate (1).

Methionine is a dietary essential amino acid as mammals lack the ability to synthesize homocysteine, its carbon skeleton, and homocysteine is not normally present in the diet. It is often the most limiting amino acid in human diets. Methylation reactions account for a large proportion of the methyl group intake in humans and the methionine synthase and BHMT reactions allows salvage of its backbone after its use for methylation.

The folate-dependent methionine cycle is sensitive to inadequate folate status. When folate status is poor,

the decreased ability to remethylate cellular homocysteine results in an increased plasma homocysteine level, and the plasma total homocysteine level is an indirect non-specific indicator of folate insufficiency. Fasting homocysteine levels are also influenced by vitamin B₁₂ status and nonfasting levels by vitamin B₆ status and methionine intake.

PHYSIOLOGY

Absorption, Transport, and Bioavailability

Folic acid does not occur in nature and is rarely found in unfortified foods and is not an active form of the coenzyme. However, it is the most common form of folate used in supplements and in fortified food products because it is highly bioavailable and chemically stable and normally is readily reduced to tetrahydrofolate, the active coenzyme form of folate. Stabilized forms of reduced folates such as 5-methyl-tetrahydrofolate are now available and are being used in some supplements. Food folates typically occur in a reduced, polyglutamyl form. Before absorption, they are cleaved to their monoglutamyl forms by a brush border glutamylhydrolase (glutamate carboxypeptidase II), sometimes called intestinal folate conjugase (15). Folates are absorbed in the proximal small intestine via the proton coupled folate transporter (PCFT) (16), an apically expressed transmembrane, pH-sensitive carrier that transports both oxidized and reduced folates with similar efficacy under the slightly acidic conditions of the gut wall. The affinities of folic acid and 5-methyl-tetrahydrofolate for the PCFT carrier are around 1 μ M (17). Transport across the basolateral membrane of the mucosal cell is via low affinity, high capacity, general anionic carriers known as multidrug resistance associated proteins (MRPs), as these proteins were originally identified as being responsible for multidrug resistance of cells to chemotherapeutic agents (17). Most dietary folate is metabolized to 5-methyl-tetrahydrofolate during its passage across the intestinal mucosa into the portal circulation and/or by first pass metabolism in the liver.

Most of the folic acid from supplements or fortified foods is also metabolized to reduced folates, primarily 5-methyltetrahydrofolate, during its passage across the intestinal mucosa and liver, and behaves similarly to reduced folates. However, low levels of free folic acid are found in fasted plasma when the diet contains folic acid and higher levels are present in nonfasted samples (18). Folic acid has to be reduced to dihydrofolate to enter the naturally occurring folate pool. This reduction, and its further reduction to tetrahydrofolate, is catalyzed by DHFR. The initial reduction of folic acid to dihydrofolate is very slow compared to its further reduction to tetrahydrofolate. Wide variations in DHFR activity have been reported for human liver (19) and it has been suggested that folic acid utilization may be impaired in individuals expressing low levels of DHFR. When high doses of folic acid or other folate forms are consumed, some are absorbed by a nonsaturable process and appear in the peripheral circulation unchanged.

The bioavailability of folic acid and reduced folate monoglutamates are usually similar and are close to 100% when consumed on an empty stomach and approximately

85% when added to, or given with, food. The bioavailability of food folate is lower and depends on the food matrix. On typical diets, food folate bioavailability is approximately 50% (20). Consequently, dietary reference intake (DRI) values are expressed in dietary folate equivalents (DFE), as folate added to food or in supplements is approximately 1.7-fold more bioavailable than food folate.

Very large doses of folic acid and other folates are well absorbed and can result in very high plasma vitamin levels. However, these fall quite rapidly as the renal threshold is exceeded and much of the dose is excreted within 24 hours. Although very high plasma folate levels can be achieved, tissue folate levels increase only marginally, often less than twofold due to the limited ability of tissues to metabolize these large doses to the polyglutamate forms required for folate retention.

Folate monoglutamate in plasma is transported into peripheral tissues via the reduced folate carrier (RFC) (21). This transmembrane carrier is specific for reduced folates with affinities in the low micromolar range while the affinity for folic acid is approximately 100-fold lower (K_t approximately 200 μ M). The liver carrier transports both folic acid and reduced folates and is thought to be PCFT. Plasma folate is normally in the 10 to 30 nM range, so RFC and PCFT would not be saturated under any physiological condition, and folate transport rates into tissues should be responsive to any change in plasma folate concentration.

A second family of closely related folate transporters known as folate-binding proteins or folate receptors (α , β , and γ) are expressed in a more limited range of epithelial tissues (17). High levels of folate-binding protein are expressed in the choroid plexus, kidney proximal tubes, and placenta and in a number of human tumors, while lower levels have been found in a variety of other tissues. The affinities of reduced folate monoglutamates for these receptors vary by receptor but are very high, usually in the low nanomolar range, while their affinity for folic acid is even higher (approximately 1 nM). This transporter is responsible for reabsorption of folate in the kidney by a receptor-mediated endocytotic process and is believed to play a similar role in folate transport in other tissues (22). Tissues that express this receptor also express PCFT, which is thought to mediate folate transport across the acidified endosomal membrane. Patients with hereditary folate malabsorption (HFM) disease, a rare autosomal recessive disorder caused by mutations in the *PCFT* gene, have a severe systemic folate deficiency and very low folate levels in the cerebrospinal fluid (CSF) (23).

An additional distinct cellular transporter responsible for the transport of reduced folate monoglutamates into the mitochondrion has been identified (24). Folic acid is not transported into the mitochondria.

Tissue Retention and Turnover

Folate monoglutamate transported into cells is metabolized to polyglutamate forms by the enzyme folylpolyglutamate synthetase. Mammalian cells contain mitochondrial and cytosolic isozymes encoded by a single gene (25). In the cytosol, much of the entering folate is metabolized to the 5-methyl-tetrahydrofolate derivative, which is a poor substrate for folylpolyglutamate synthetase (25). This has to be metabolized to tetrahydrofolate via the methion-

ine synthase reaction before effective polyglutamylation and tissue retention is achieved. As the flux of 5-methyl-tetrahydrofolate through the methionine synthetase reaction is quite limiting, particularly when the cell contains high levels of 5-methyl-tetrahydrofolate polyglutamate, much of the newly absorbed folate would not be retained by the tissue and would appear in the circulation predominantly as 5-methyl-tetrahydrofolate.

Under normal conditions of dietary intake and status, whole body folate turns over quite slowly with a half-life in excess of 100 days (26). Urinary excretion of intact folate accounts for only a very small proportion of this turnover. Over 99% of tissue folate is in the polyglutamate form. The actual mechanism of catabolism is poorly understood but primarily involves cleavage at the C9-N10 bond to generate *p*-aminobenzoylpolyglutamates and a pterin moiety (27). The *p*-aminobenzoylpolyglutamates are hydrolyzed to the monoglutamate by a lysosomal glutamylhydrolase and acetylated, and then excreted in urine as *N*-acetyl-aminobenzoylmonoglutamate. The pterin moiety is excreted in bile and appears in the feces.

Feces contain very high levels of folate but most, if not all, of this arises from bacterial synthesis in the lower gut. Studies in rodents have shown that some of this bacterially synthesized folate is bioavailable (28). Whether folate synthesized by gut bacteria in humans is also bioavailable has not been determined.

FOLATE DEFICIENCY

Megaloblastic Anemia

Folate deficiency is usually due to a dietary insufficiency, although it can arise from other causes such as malabsorption syndromes. The classical symptom of folate insufficiency is megaloblastic anemia, a condition reflecting deranged DNA synthesis in the erythropoietic cells. Folate deficiency resulting in megaloblastic anemia is a fairly common condition in pregnancy. Blood cells are enlarged and often multinucleated. Megaloblastic changes occur in all fast growing tissues such as the marrow and the gut epithelia. Megaloblastic cells contain close to twice the normal DNA content and the DNA is partially fragmented. Many cells are arrested in the G2 phase just prior to mitosis. Cells that divide often undergo apoptosis. The defect in DNA synthesis in folate deficiency has been ascribed to defective thymidylate synthesis under these conditions with a resulting increase in uracil misincorporation into DNA. Removal of uracil by the repair enzyme uracil DNA glycosylase, and a decreased repair of the gaps produced by this enzyme, would lead to an increase in double-stranded DNA breaks under these conditions (29).

Megaloblastic anemia or pernicious anemia is also a classical symptom of impaired B₁₂ status. This condition, which is quite prevalent in the elderly, is seldom due to a dietary deficiency but usually results from malabsorption of B₁₂. However, the anemia that results is identical to that of folate deficiency. In B₁₂ deficiency, the B₁₂-dependent methionine synthase enzyme is inactive and cytosolic folate is "trapped" as 5-methyl-tetrahydrofolate at the expense of other folate coenzyme forms required for one-carbon metabolism such as thymidylate synthesis, leading to a functional folate deficiency in the cell

(13). As 5-methyl-tetrahydrofolate is a poor substrate for folylpolyglutamate synthetase, the ability of tissues to accumulate folate is reduced and the functional folate deficiency is compounded by a drop in cellular folate levels. As the defective DNA synthesis in pernicious anemia is caused by an induced secondary folate deficiency, high levels of folate can cause a hematological response in patients with megaloblastic anemia due to B₁₂ deficiency, but folate is ineffective in preventing the severe neurological pathologies associated with B₁₂ deficiency.

Vascular Disease

Severe genetic conditions that result in very marked hyperhomocysteinemia are associated with a variety of clinical symptoms including early onset occlusive cardiovascular and cerebrovascular disease. These genetic diseases include MTHFR deficiency and CBS deficiency, enzymes involved in the homocysteine remethylation and transsulfuration pathways, respectively. Lowering of homocysteine with high doses of folate and betaine improves the clinical picture in these patients, strongly suggesting that homocysteine is the causative agent of these conditions, although the actual mechanism has not been definitively established (30).

Many epidemiological studies have suggested that chronic *mild* hyperhomocysteinemia is a risk factor for occlusive vascular disease. In many case-control studies, plasma homocysteine concentrations in patients with vascular disease were higher than in matched controls. However, this relationship has not been found consistently in prospective studies. Fasting homocysteine levels have been inversely correlated with both plasma folate and food folate intake and increased folate intake lowers the mean homocysteine of groups, with the greatest effect on those with the highest initial plasma homocysteine levels. If mildly elevated homocysteine is a causative risk factor for vascular disease, then it may be that a simple dietary intervention can lower the risk. However, recent randomized controlled trials with folic acid (and vitamins B₁₂ and B₆) have not found any benefit in reducing recurrence rates of cardiovascular events (31), although some benefit has been reported for stroke recurrence (32). Homocysteine levels were, as expected, significantly reduced in the B vitamin-treated group in these trials. Although results from recurrence rate trials do not support a role for B vitamin supplements in reducing the risk of cardiovascular events, the populations under study were quite elderly and had a previous event, and the studies may have been underpowered to observe a small effect. It may be that B vitamin supplements could have a benefit earlier in life before any putative damage caused by elevated homocysteine has occurred.

A common polymorphism (677 C→T, Ala to Val) in the flavoprotein MTHFR that results in a "heat-labile" enzyme and decreased enzyme activity in tissues has been implicated as one reason for the folate responsiveness of a subset of hyperhomocysteinemic subjects (33). The incidence of the Val/Val homozygote (around 10% in the U.S. population) is significantly increased in subjects with the highest deciles of homocysteine levels. The valine substitution reduces the affinity of the enzyme for its flavin

adenine dinucleotide (FAD) cofactor, and the loss of FAD leads to decreased protein stability. Folate binding "locks" the FAD cofactor in place on the enzyme and stabilizes the protein (34). Comparisons of Val/Val individuals with Ala/Ala subjects have demonstrated that differences between these groups are most obvious in subjects with both poor folate and riboflavin status and that increased dietary folate not only lowers homocysteine in both groups but also eliminates the differences between the genotypes (35). Many case-control studies have suggested that the 677 T allele in MTHFR is associated with vascular disease risk although prospective studies have been equivocal. There is a large variation in penetrance of this polymorphism among different ethnic groups and this may have confounded some of the case-control studies.

Neural Tube Defects

In the early 1990s, double-blind randomized trials confirmed that supplemental folic acid given prior to conception and during early pregnancy significantly reduced by over 70% the occurrence and recurrence of neural tube defects (NTDs), the most common birth defects in humans (36–38). This was most likely not due to correction of a simple folate deficiency. Instead, it is thought that some women and/or their offspring have a higher requirement for folate due to genetic reasons. Later a very large population-based study in China showed that folic acid supplements (400 µg/day) reduced NTD occurrence by 79% in a high incidence region and 41% in a low incidence region, and the underlying incidence refractory to folate supplementation was similar between regions (39). The current fortification of the food supply with folic acid in the United States and some other countries arose because those individuals at risk for having an NTD child cannot be identified at the moment.

A large number of folate candidate genes have been screened as risk factors for NTDs. Homozygosity for offspring with the 677 T (Val) allele of MTHFR has been shown to be a risk factor in a number of studies with the risk increasing very significantly in comparisons of offspring of mothers with poor folate status. However, carrying this particular allele can only account for approximately 15% of the population-based attributable derived risk (40), and the vast majority of offspring that are homozygous for the 677 T allele do not develop NTDs.

Cancer

Epidemiological studies have shown that poor folate status is associated with an increased risk for certain types of cancer including colon cancer (41). The mechanism behind this is not known, but uracil misincorporation arising from defective thymidylate synthesis has been suggested as one possibility, as this would influence both DNA synthesis and repair. As changes in folate status influence the remethylation of homocysteine to methionine and alter adenosylmethionine to adenosylhomocysteine ratios, it has also been proposed that the increased cancer risk in folate deficiency may be due to hypomethylation of DNA and/or histones. Changes in DNA and histone methylation have been observed in many tumors and it has been demonstrated that methionine deficiency causes hypomethylation of DNA.

Subjects homozygous for the MTHFR 677 T allele demonstrate a decreased cancer risk that is most pronounced in comparisons of subjects of good folate status (41). It has been shown that this polymorphism can direct more of the one-carbon flux into thymidylate synthesis and incorporation into DNA, and away from methionine synthesis (42). Normally, 5-methyl-tetrahydrofolate is the only form of folate found in plasma and the red cell. However, significant amounts of 10-formyl-tetrahydrofolate are seen in red cells of some MTHFR 677 T subjects (42), also indicating some redirection of the one-carbon metabolic flux. The reduced flux into methionine synthesis in MTHFR 677 T subjects may argue against hypomethylation in folate deficiency being responsible for the increased cancer risk.

INDICATIONS AND USAGE

Supplementation to Achieve Recommended Intake Levels

In 1998, the United States Food and Nutrition Board of the National Academy of Sciences and a joint FAO/WHO Expert Consultation on Human Vitamin and Mineral Requirements reviewed their recommendations for folate intake (20). Both groups used plasma and red blood cell folate concentrations as primary indicators of folate adequacy, and plasma total homocysteine levels as an additional indicator of folate status. Their conclusions appear in Table 2.

The suggested levels represent the daily dietary folate required to ensure adequate nutrition in 97.5% of the population and are an overestimation of the level needed for most people in any given group. Individuals who do not routinely consume the suggested level of folate from

foods should be encouraged to supplement their diets with folate.

Treatment of Folate Deficiency

Folate deficiency has traditionally been diagnosed as a low serum or red blood cell folate level [<3 ng/mL (7 nM) and <160 ng/mL (360 nM) respectively] in the setting of macrocytic anemia. However, anemia reflects a late stage of folate depletion; earlier stages are often evidenced solely by low blood folate levels and/or elevations in homocysteine levels. Vitamin B₁₂ deficiency artifactually increases serum folate levels and decreases red blood cell folate levels, and also increases plasma homocysteine levels, which can confound the diagnosis.

After ruling out a B₁₂ deficiency, rapid restoration of a folate-replete state can be achieved by administering 500 to 1000 μ g of folic acid orally per day. There is little evidence that doses greater than 1000 μ g convey additional benefit. Once the folate deficiency is resolved, daily intake of folate based on the levels found in Table 2 should be maintained. In cases of severe intestinal malabsorption or an inability to use the gastrointestinal tract, it may be necessary to administer 1 mg of folic acid parenterally via an intravenous or intramuscular route. This dose appears suitable for initial repletion of a folate-deficient state.

Prevention of Neural Tube Defects

Because the neural tube closes during the fourth week of embryonic life before many women realize they are pregnant, and the population at risk for this condition cannot be identified, it is recommended that all women planning a pregnancy or are capable of becoming pregnant take 400 μ g folic acid, either as a supplement and/or in fortified foods in addition to normal dietary intake (20). This recommendation is based on the intervention trials and it is not known whether lower levels of supplementation would be as effective. It should be noted that this recommendation is distinct from the DRIs for pregnancy. Few pregnant women would receive the recommended dietary allowances (RDA) of 600 μ g from their diet and it would be practically impossible to increase dietary folate intake by the additional 680 μ g that would be equivalent to the 400 μ g folic acid supplement recommended for NTD protection. Women with a family history of NTDs or who have had a previous NTD-affected pregnancy should be encouraged to take a daily supplement containing 4 mg folic acid during the periconceptual period.

Beginning in 1998, the FDA mandated fortification of the U.S. food supply with folic acid to reduce the incidence of NTDs. Food fortification rather than targeting supplements to women planning pregnancies was deemed necessary because of a perceived failure of public health efforts to influence those most at risk. Fortification was planned at a level expected to achieve an average extra daily folic acid intake of 100 μ g, which would be equivalent to approximately 170 μ g of extra food folate because of its higher bioavailability, and with few individuals expected to receive over 1 mg, to limit the possibility of masking of B₁₂ deficiency. Because of "overage" by food manufacturers, the average increased folic acid intake in the U.S. population was initially closer to 200 μ g

Table 2 RDIs for Folate

RDA		^a RNI	
Age	μ g DFE ^b /day	Age	μ g DFE/day
0-5 mo	65	0-6 mo	80
6-11 mo	80	7-12 mo	80
1-3 yr	150	1-3 yr	160
4-8 yr	200	4-6 yr	200
9-13 yr	300	7-9 yr	330
14 yr and above	400 ^c	10 yr and above	400
Pregnancy	600	Pregnancy	600
Lactation	500	Lactation	500

Recommended Dietary Allowances (RDA, 1998 United States Food and Nutrition Board of the Institute of Medicine) and Recommended Nutrient Intakes (RNI, 1998 Joint FAO/WHO Expert Consultation on Human Vitamin and Mineral Requirements). Values given for the FAO/WHO Expert Consultation are provisional values published in a preliminary report.

^aValues for males and females in all age groups were combined as they did not differ, and age groups with the same RNI were combined.

^bValues are given as dietary folate equivalents (DFE). 1 DFE = 1 μ g food folate = 0.6 μ g synthetic folic acid taken with food = 0.5 μ g synthetic folic acid taken on an empty stomach.

^cIn view of evidence linking increased folate intake with reduction of neural tube defects in the fetus, it is recommended that all women capable of becoming pregnant consume 400 μ g synthetic folic acid from supplements and/or fortified foods in addition to intake of food folate from a varied diet. The RDA value for pregnancy does not include this additional folate.

and is now approximately 140 μg (equivalent to approximately 240 μg food folate). Postfortification NTD rates have fallen by approximately 26% in the United States (43). Some argue that increased fortification is required to further decrease NTD rates and point to the 70% reduction observed in the initial intervention trials. However, NTD rates had been falling prior to fortification and the underlying rate in the United States was quite low compared to some other countries. The folate intervention studies in China demonstrated a 70% drop in NTD rates in areas of high prevalence and a much smaller drop in areas of lower prevalence (39). In Canada, which fortifies at a level similar to the United States, but has better NTD ascertainment, the estimated reduction was approximately 46% with more dramatic reductions in provinces with higher prefortification prevalence rates (44). It is likely that the current level of fortification has already prevented most, but not all, folate-responsive NTDs. Food fortification has exposed the whole population to a very significant increase in folate intake, not just the individuals at risk for NTDs. Concerns have been raised about the possibility of unanticipated side effects, as limited studies have been carried out on the effects of high doses of folate (see later).

Although fortification was initiated to reduce NTD incidence, there may have been other benefits. Plasma and red cell folate levels have increased and the proportion of the population with deficient levels has fallen dramatically. The proportion of the population with elevated plasma homocysteine levels has also fallen by approximately 50% (45), and vitamin B₁₂ status rather than folate status is now the major determinant of fasting homocysteine levels in the U.S. population.

Adverse Effects of Drugs on Folate Status

Treatment with certain drugs may indicate the need for administration of supplemental folate. For instance, many physicians prescribe methotrexate (7.5–15 mg/week) for the treatment of rheumatoid arthritis, asthma, and ulcerative colitis. Side effects of this treatment, including alopecia, stomatitis, pancytopenia, and interstitial pulmonary fibrosis, are thought to be inversely related to serum folate levels at the start of treatment. Daily administration of 1 mg of folic acid to people who take methotrexate appears to significantly reduce the development of side effects, and does not interfere with the efficacy of treatment (46).

Long-term use of sulfasalazine, an anti-inflammatory that is often administered for the treatment of inflammatory bowel disease or rheumatoid arthritis, is often associated with folate deficiency. Therefore, prophylactic coadministration of folic acid at 400 to 1000 μg /day is indicated.

Phenytoin, phenobarbital, and primidone have repeatedly been associated with either low serum folate levels or frank folate deficiency. Therefore, chronic administration of these drugs should also prompt prophylactic administration of 400 to 1000 μg of folic acid per day.

Chronic alcoholism is associated with a considerable risk of folate deficiency. A large part of this effect can be explained by the fact that the diet of a chronic alcoholic is often folate poor. However, other mechanisms

have also been described, including impaired intestinal deconjugation of polyglutamated food folates, increased metabolic turnover or urinary excretion, and cleavage of the folate molecule by acetaldehyde. Since deficiencies of other B vitamins commonly accompany folate deficiency in this setting, administration of a multivitamin containing 400 μg of folic acid is probably the best approach to avoid development of deficiency.

Hyperhomocysteinemia

Although very high levels of homocysteine can cause vascular disease, the evidence that modest elevations in plasma homocysteine increase risk is not that compelling. Because the cost of treating hyperhomocysteinemia with vitamins is exceedingly low, hyperhomocysteinemia remains a reasonable indication for B vitamin supplementation. Some contend that this is particularly true for the secondary prevention of cardiovascular disease when other reversible risk factors cannot be identified. Some potential adverse effects of B vitamin supplement have been reported in the vascular disease recurrence trials with folate, B₁₂, and B₆, primarily due to the B₆ component (31). While this remains to be confirmed, it is probably prudent to limit supplements to RDA levels, which for most people would be sufficient for maximal reduction of homocysteine.

In healthy ambulatory populations, low dietary intake and low blood levels of folic acid, B₁₂, and B₆ are the primary determinants of blood homocysteine levels (47). It is clear that daily administration of these three vitamins reduces blood homocysteine levels to levels associated with considerably lower cardiovascular risk, at least in some studies. Administration of a daily dose of 400 μg of folic acid often suffices, with two notable exceptions. If hyperhomocysteinemia is due to a deficiency of B₁₂ or B₆, folate supplementation will not help. Secondly, the hyperhomocysteinemia that commonly develops in individuals with chronic renal insufficiency and in postrenal transplant recipients is particularly resistant to low doses of folic acid supplementation (48). It appears that doses of 2.5 mg of folic acid per day are necessary for optimal homocysteine reduction in this population. Normalization of homocysteine levels in individuals with end-stage renal disease may never occur, even with supraphysiological doses of folic acid.

Cancer Prevention

Observational studies continue to indicate an inverse relationship between folate intake or folate blood levels and the risk of developing certain common cancers, and data from animal experiments support a true causal relationship. Ecological studies with folate supplement users have also indicated a protective effect. However, limited clinical intervention trials on colon polyp recurrence have failed to show any benefit of a 1 mg/day supplement of folic acid. Some adverse effects on other cancers were noted, but the evidence for this is weak (49). Additional clinical intervention trials are in progress but results are not currently available.

A study of colon cancer rates in the United States and Canada suggested a slight increase or blip during the period 1996 to 1999, and it was hypothesized that this

may have been due to the introduction of folic acid fortification in these countries (50). While possible, these data could also be explained by confounders such as the introduction of routine colonoscopies around this time. Approximately one-third of the U.S. population take vitamin supplements, usually containing 400 μg folic acid, which is much higher than the extra folic acid intake obtained from food fortification. It is difficult to reconcile the hypothesis that food fortification has increased cancer risk with the many other studies indicating that folic acid supplements reduce cancer risk.

The appropriate setting for prophylaxis with folic acid for cancer prevention remains inconclusive, in part due to this concern about potential risks. In large doses, folate is known to accelerate the growth of existing cancers. Therefore, there is concern that supplemental folate may inadvertently accelerate the growth of a precancerous or cancerous polyp in the colon. However, it might well be that normal folate status is sufficient to promote growth of cancerous lesions, and the epidemiological data are best explained by poor folate status being a risk for cancer development. It is prudent to await further research on this topic before folic acid is used for cancer prevention in individuals at increased risk.

CONTRAINDICATIONS

Vitamin B₁₂ Deficiency

Vitamin B₁₂ deficiency is often undiagnosed and may affect a substantial percentage of the population, particularly the elderly. It may be associated with hematologic symptoms (megaloblastic anemia) and/or neurologic symptoms (dementia, paresthesia, and ataxia). People who have, or are at risk for, vitamin B₁₂ deficiency should not be given folic acid without concomitant monitoring for and treatment of vitamin B₁₂ deficiency. One risk of folic acid supplementation is that high doses can prevent (mask) the hematologic manifestations of B₁₂ deficiency, and thus delay diagnosis, while allowing the associated neurologic complications to progress. Furthermore, there is anecdotal evidence suggesting that folic acid supplementation may precipitate or exacerbate the neurologic damage of vitamin B₁₂ deficiency. This was also suggested by a recent population-based study comparing functional markers of B₁₂ deficiency (such as methylmalonic acid) in subjects with low serum B₁₂, which showed that a subset of this population with the highest plasma folate levels had increased levels of these indicators of B₁₂ deficiency (51). While consistent with exacerbation of B₁₂ deficiency by high folate, it should be noted that the subgroup with the highest folate levels were almost certainly supplement users and these supplements would also have contained vitamin B₁₂. Selecting for those with high folate and low B₁₂ would probably be selecting for a group with severe malabsorption of B₁₂.

PRECAUTIONS AND ADVERSE REACTIONS

Drug Interactions

In large amounts, folic acid has been reported to counteract the antiepileptic effect of phenobarbital, phenytoin,

Table 3 Upper Limits for Folic Acid Set by the 1998 Food and Nutrition Board of the National Academy of Sciences

Age (years)	Upper limit ($\mu\text{g}/\text{day}$)
1-3	300
4-8	400
9-13	600
14-18	800
>19	1000

and primidone and increase the frequency of seizures in susceptible individuals. Because of the drug-nutrient interaction between these anticonvulsant drugs and folate, people taking these three drugs are also at risk of folate deficiency.

Overdosage

Folic acid doses of up to 15,000 μg in healthy adults without convulsive disorders have not been associated with any reported serious adverse effects. The Food and Nutrition Board of the National Academy of Sciences recommended 1000 μg as an upper limit for folic acid for adults 19 years and older, including pregnant and lactating women (20). This upper limit, which refers to supplemental folic acid and not food folate, was not related to any known toxicity of folate per se. Instead, the concern was the possible masking of B₁₂ deficiency anemia and limited information, primarily anecdotal, that folate might exacerbate the neurological manifestations of B₁₂ deficiency. The Food and Nutrition Board set upper limits for children and adolescents by adjusting the adult limit on the basis of relative body weight. Table 3 gives the upper limits for folic acid by age group. No upper limit was set for infants due to lack of adequate data. The Food and Nutrition Board also recommended that food (or maternal milk) be the only source of folate for infants.

Circulating Folic Acid

Fortification of the food supply with folic acid and supplement use has resulted in the appearance of low levels of free folic acid in the circulation. Concerns have been raised about the presence of this unnatural form of the vitamin in the circulation, although there is no credible evidence currently available to suggest that there are any harmful effects unique to folic acid itself as opposed to other forms of the vitamin. It is possible that the extremely tight binding of folic acid to the folate receptor could interfere with transport of other folates that utilize the folate receptor for entry into tissues. The fate of plasma folic acid would differ from reduced folates such as 5-methyltetrahydrofolate in that its removal from the circulation would primarily involve tissues that express the folate receptor and/or PCFT as opposed to most peripheral tissues that express the RFC.

One study has related circulating folic acid to a reduction in natural killer cell number although the significance of this is not clear (52). Another has related circulating folic acid and high folate to impaired cognitive function (53), although this is at odds with other studies reporting that folic acid supplements improve cognitive function in the elderly (54).

French Maritime Pine

Peter J. Rohdewald

INTRODUCTION

Pycnogenol® is the registered trade name for a special standardized extract from the bark of the French maritime pine (*Pinus pinaster* ssp. *atlantica*), distributed exclusively by Horphag Research, U.K. The spray-dried, powdered extract is marketed worldwide as a food supplement, as herbal medicine, as an active cosmetic ingredient, as well as in functional foods.

The traditional use of pine bark was related to treatment of scurvy and wound healing. Currently, Pycnogenol is used to restore capillary integrity in cases of gingivitis, retinopathy, edema, and hemorrhoids. Other fields of application are connected to improved endothelial function with corresponding improved blood flow, relieving high blood pressure, and prevention of platelet aggregation. The anti-oxidant activity was found to improve attention-deficit/hyperactivity disorder (ADHD) symptoms in children and cognitive function in elderly citizens. Human pharmacologic studies point to significant anti-inflammatory activity and Pycnogenol was shown to be effective in diverse pathologies, such as osteoarthritis, dysmenorrhea, endometriosis, asthma, and sunburned skin. More recently, a potent inhibition of α -glucosidase by the high-molecular-weight procyanidin species was identified. Several clinical studies have shown a glucose-lowering effect of Pycnogenol, also when taken in addition to oral anti-diabetic medication. Safety of Pycnogenol is well documented, corroborated by experience with 7000 patients in numerous clinical trials carried out to date. Pycnogenol has GRAS (generally recognized as safe) status in the United States. Unwanted effects are mild and transient, and no interactions with drugs have been reported.

BACKGROUND

Raw material:

- Family: Pinaceae
- Genus: *Pinus*
- Species: *Pinus pinaster* Aiton, ssp. *atlantica* D. del Villar
- Part used: Outer bark

P. pinaster ssp. *atlantica*, the Atlantic maritime pine, is cultivated in large monocultures in South Western France in the Biscay area (Fig. 1). It is distinguished from other species by the thick, deeply fissured, reddish bark, representing a geographic race adapted to harsh climate and sandy soil. Trees are cut for timber production after cultivation for 30 to 50 years, and the fresh outer bark is used

Figure 1 Forest of French maritime pine trees.

for extraction throughout the year. The bark pieces are 1 to 3 cm thick, and they are formed from up to 50 mussel-shaped, deep red or light brown layers. The inner side of the bark is slightly concave and plane, while the outer part is irregular with deep cut V-shaped fissures.

Traditionally, preparations from pine bark had been used in the Middle Ages for wound healing, as referred to in the *Thesaurus Medicaminum* of the Zurich pharmacist H. Minner (1479). Also, in North America, Native Americans used bark from conifers for wound healing, and to treat scurvy (1).

CHEMISTRY AND PRODUCTION

Composition

Pycnogenol represents a concentrate of phenolic compounds, consisting of phenolic acids, catechin, taxifolin, and procyanidins (2).

Figure 2 Procyanidin with type 4–8 bonds. Monomers could be catechin or epicatechin units.

Pycnogenol consists predominantly of procyanidins, condensed catechin, and epicatechin in various chain lengths up to dodecamers (Fig. 2). The catechin–epicatechin units can be linked by C4–C8 bonds or by C4–C6 bonds, with the C4–C8 linked isomers predominating. The extract is standardized to contain $70\% \pm 5\%$ procyanidins in accordance with the USP for maritime pine bark extract.

Further to the procyanidins, monomeric flavan-3-ol species are present in Pycnogenol with catechin as the main monomeric procyanidin and only traces of epicatechin. Taxifolin is available in free form and as taxifolin glucoside.

Furthermore, the extract bears several phenolic acid species, which are derivatives of benzoic acid—*p*-hydroxybenzoic acid, protocatechic acid, vanillic acid, and gallic acid—or of cinnamic acid, *p*-cumaric acid, caffeic acid, and ferulic acid. Glycosides and glucose esters of these phenolic acids have been identified in the extract.

As inorganic ions, calcium, potassium, and iron are present, together with traces of manganese, zinc, and copper (3).

Production

The extract is prepared from fresh sorted, cleaned, and crushed bark. The patented extraction process chain uses ethanol and water as solvents in a multistep process. The purified aqueous extract is spray dried and represents a very fine, red to brownish-colored powder with an aromatic smell and astringent taste. It is soluble in water and short-chained alcohols and ketones (i.e., ethanol, glycerol, acetone) and insoluble or sparingly soluble in oils. One thousand kilograms of bark is needed to produce 1 kg Pycnogenol.

Formulations

Pycnogenol is available as tablets or capsules of 20 to 100 mg. For oral health care, a mouth spray delivering 2 mg per actuation and a chewing gum containing 5 mg Pycnogenol are available. As Pycnogenol is water soluble, it is available in functional drinks. A wide range of cosmetic products containing the extract is sold worldwide.

Analysis

The quality of the bark of *P. pinaster* is controlled according to the monograph “Maritime Pine Extract” of the *United States Pharmacopoeia* and *The National Formulary* (4).

The standardized extract, Pycnogenol, corresponds to the monograph: “Maritime Pine Extract” of the *National Formulary of the US Pharmacopoeia* (4) in terms of identity and purity using thin layer chromatography (TLC) and high-performance liquid chromatography (HPLC). The content of procyanidins is standardized to $70\% \pm 5\%$, quantified spectrophotometrically after oxidative hydrolysis.

Stability

Pycnogenol, stored and protected from light and humidity in well-closed containers at room temperature, is stable over a period of 3 years.

PRECLINICAL STUDIES

Circulatory Function

Stimulation of e-NOS

Pycnogenol stimulates the activity of endothelial nitric oxide synthase (e-NOS) in vitro and in vivo (Fig. 3). In isolated aortic rings from rats (2) as well as in human spermatozoa (R Stanislavov MD and V Nikolova PhD, 2007, unpublished results), it stimulated endothelial NO production from natural substrate L-arginine by e-NOS. Nitric oxide (NO) initiates the release of cyclic 3',5'-guanosine monophosphate (cGMP) in smooth muscle cells and leads to vasorelaxation. Furthermore, NO reacts with blood platelets and prevents their aggregation.

Inhibition of Adrenaline-Induced Vasoconstriction

Both adrenaline as well as noradrenaline are very potent vasoconstrictors. In experiments with isolated aortic rings

Figure 3 Scheme for enhanced NO production by increasing synthesis of endothelial NOS.

from rats, Pycnogenol inhibited the vasoconstriction induced by these stress hormones. The effect was dose dependent and could not be observed after removal of the endothelium (2).

Antihypertensive Effect

In vitro, Pycnogenol inhibits the angiotensin-converting enzyme (ACE), while in rats, blood pressure could be reduced significantly after i.v. injection (2).

Capillary Integrity

Protein Binding

Procyanidins, the main constituents of Pycnogenol, belong to the class of nonhydrolyzable tannins and have a high affinity to proteins. Pycnogenol binds selectively to collagen, elastin, and skin powder, whereas binding to egg albumin is low (5). Also, the interaction with enzymes is specific, as a result of the differing IC_{50} values (3) for inhibition of various enzymes. Stabilization of membranes of erythrocytes via protein binding may be the cause of prevention of hemolytic injury in glucose-6-phosphate dehydrogenase-deficient human erythrocytes (6).

Capillary Sealing

Spontaneous hypertensive rats show a pathologically high leakage of capillaries. Feeding with Pycnogenol produced a long-lasting, dose-dependent increase of capillary resistance against a topically applied vacuum (2).

Anti-inflammatory Activity

Radical Scavenging Activity

In several in vitro models, Pycnogenol inactivated superoxide and hydroxy radicals as well as inhibited the formation of singlet oxygen and nitric oxide radicals (2,3). The superior capacity of procyanidins in radical scavenging is based on their ability to retain scavenging activity by intramolecular rearrangements (2). The lifetime of the ascorbyl radical is prolonged by Pycnogenol to a greater extent than by other bioflavonoids (3), and the oxidation of low-density lipoprotein (LDL) was inhibited in vitro (3). DNA was protected against iron/ascorbate-induced strand breaks by Pycnogenol (3). Toxicity of free radical producing anti-tumor drugs was reduced by pretreatment of mice with Pycnogenol without reducing the anti-cancer activity of doxorubicin and cyclophosphamide (7).

Antioxidative Effects in Biological Systems

Incubation with Pycnogenol protected α -tocopherol in endothelial cells against oxidation by peroxynitrite (3), protected nerve cells against β -amyloid or glutamate-induced toxicity (2,3), and inhibited peroxidation of retinal lipids more efficiently than vitamins E and C (2). Neurons were protected from amyloid- β -peptide-induced apoptosis (8).

Stimulation of Synthesis of Antioxidative Substances

Pycnogenol incubation doubles the concentrations of antioxidative enzymes in vascular endothelial cells (2). Synthesis of proteins in macrophages is increased, and activity of antioxidative enzymes, like catalase or superoxide dismutase, is dose dependently enhanced (2).

Interaction with NF- κ B

In a murine macrophage cell line, preincubation with Pycnogenol blocked the activation of nuclear factor kappa B (NF- κ B) and the activator protein (AP-1), major transcription factors centrally involved in inflammatory processes (9). In a human lymphocyte cell line, the extract inhibited the transcription factors nuclear factor for activated T-cells (NF-AT) and AP-1 (9). It also prevented the UV-induced activation of transcriptional factors NF- κ B and AP-1 in human cell lines from fibroblasts and keratinocytes (2). In human endothelial cells, pretreatment with Pycnogenol suppressed the activation of NF- κ B by tumor necrosis factor- α (TNF- α) (2). These results indicate that proinflammatory responses can be inhibited by Pycnogenol early in the biochemical reaction chain at the transcriptional level.

Inhibition of Inflammatory Mediators

At the level of cytokines, Pycnogenol blocks production of interleukins 1, 2 (9), 6, and 10 (2). Synthesis of inducible NOS is blocked by preincubation of macrophages with Pycnogenol (3), and the release of histamine from mast cells is inhibited in vitro (2).

Inhibition of Adhesion Molecules

Intercellular adhesion molecules are necessary for tissue invasion of leukocytes in inflammatory processes. Pycnogenol pretreatment downregulates expression of intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) (2).

Inhibition of Matrix Metalloproteases

Matrix metalloproteases (MMPs) destroy collagen and elastin. Pycnogenol and its metabolites inhibit MMP1, MMP2, and MMP9, and furthermore prevent the release of MMP9 from human monocytes (6).

Inhibition of UV-Induced Damage

Topical application of a Pycnogenol-containing gel significantly prevented erythema formation after UV radiation (2) and inhibited photocarcinogenesis (10). Wound healing was accelerated and scar formation reduced following application of 1% to 2% Pycnogenol in gels (11).

Age-Related Degenerative Processes

Stimulation of Immune System

Incubation with Pycnogenol augmented phagocytosis in macrophages (12). Feeding of the extract to immunosuppressed mice provided protection against protozoal infection (13), and to senescence-accelerated mice restored levels of progenitor cells and β - and T-lymphocytes in a dose-dependent manner (2). Oral administration of Pycnogenol to retrovirus infected mice (2) or mice inoculated with cancer cells (14) showed enhanced natural killer cell activity.

Enhancement of Cognitive Function

Administration of Pycnogenol to senescence-accelerated mice significantly enhanced the memory retention rate in a dose-dependent manner compared to nonsupplemented mice in step-through and step-down tests. The treatment also significantly improved the cognitive behavior in the shuttle box test (2).

Antiaging Effects

The life span of mice was prolonged after oral administration of a Pycnogenol-containing combination of antioxidants (15). That of drosophila was increased after feeding the extract (16).

Spasmolytic Activity

Phenolic constituents of Pycnogenol, ferulic acid, and caffeic acid, possess spasmolytic activity as demonstrated in vivo on the isolated rat uterus (2) as well as in vivo in experiments with rats (2).

Blood Glucose Lowering

In streptozotocin-induced diabetic rats, Pycnogenol feeding lowered blood glucose concentrations and enhanced concentrations of antioxidative substances in blood (17).

Proposed Mechanisms of Action

Based on the support of NO production, Pycnogenol offers a range of pharmacological effects on the vascular system, such as increased microcirculation, improvement of erectile function, antihypertensive effects, and inhibition of platelet aggregation. The enhancement of capillary integrity results in an anti-edema effect and prevents microbleedings. Its radical scavenging potency may contribute to the anti-inflammatory actions and beneficial effects in degenerative diseases. The spasmolytic activity of phenolic acids contained in Pycnogenol is probably related to its activity in reducing premenstrual cramps and pain. The lowering of blood glucose in streptozotocin-induced diabetic rats points to an anti-diabetic effect.

Safety Studies (On File at Horphag Research Ltd., U.K.)

Animal Toxicology

The *absence of mutagenic* effects has been shown using the Ames test, the chromosome aberration assay in human lymphocytes and the micronucleus test in mice.

Acute toxicity is very low. Fourteen acute toxicity tests had been performed using three different species and oral, subcutaneous, intraperitoneal, and intravenous routes of administration. LD50 data varied after oral administration from 1000 to 4000 mg/kg.

Chronic toxicity had been tested in three species after oral administration. The no observed adverse effects level (NOAEL) was established as 100 mg/kg/day.

In six *reproduction toxicity* studies with three species no teratogenic effects were detected, no signs of perinatal toxicity, or negative effects on fertility were noted.

Tolerance after topical application was tested in several models. Skin and eye irritation tests in rabbits and contact hypersensitivity test in guinea pigs showed that Pycnogenol is nonirritating. In human volunteers, no skin irritation was found with the patch-occlusion test.

Bioavailability, Absorption, Metabolism, and Excretion

Healthy volunteers took a single dose of 300 mg Pycnogenol or 200 mg daily for five days to reach steady state conditions in a pharmacokinetic investigation (18). Plasma samples taken at defined time points were analyzed by HPLC. Monomeric molecules, such as catechin, caffeic acid, ferulic acid, and taxifolin were found in plasma within 30 minutes. The primary metabolite devel-

oping from procyanidins was δ -(3,4-dihydroxy-phenyl)- γ -valerolactone, which appeared in the blood stream four hours after intake. Another 10 unidentified metabolites were found in plasma.

Urinary excretion of Pycnogenol constituents and metabolites was investigated in human volunteers at different time point post consumption. After oral intake, four metabolites could be found in the urine of a human volunteer. Taxifolin and ferulic acid were excreted as glucuronides or sulfates after 1 to 4 hours (2). Another investigation found a maximum excretion of ferulic acid after intake of Pycnogenol at 17 hours (3). Procyanidins had been metabolized to valerolactones, such as δ -(3,4-dihydroxy-phenyl)- γ -valerolactone, which are excreted as glucuronides after 8 to 15 hours (2).

CLINICAL STUDIES

Anti-oxidant Activity

Pharmacologic Investigations

Healthy volunteers were supplemented with 150 mg Pycnogenol daily for six weeks. The oxygen radical absorbance capacity (ORAC) of blood plasma increased significantly by 40% after three and six weeks, as compared to baseline. After a four-week washout period, the ORAC value dropped to almost baseline values (19).

Participants diagnosed with erectile dysfunction were supplemented with 120 mg Pycnogenol a day, a control group received placebo. After three weeks, the Pycnogenol group showed a statistical significant increase of the "ferric reduction activity of plasma" (FRAP) values as compared to placebo (20).

A decrease of markers indicative for oxidative stress was identified in some studies. Plasma F2-isoprostanes, metabolites developed from oxidized lipids, decreased significantly in the elderly in a double-blind placebo-controlled study after three months intake of 150 mg Pycnogenol a day, while placebo had no effect (21). Oxidative DNA damage was evaluated in children treated with Pycnogenol for improving symptoms related to ADHD (22). Blood lymphocyte were analyzed for 8-oxo-7,8-dihydroguanine (8-oxoG) and their presence decreased significantly after one-month treatment with Pycnogenol, while the placebo did not show any change. The decreased 8-oxoG values returned to baseline values after one-month discontinuation of Pycnogenol.

Improvement of Spermatozoa Quality

Lack of anti-oxidants has been connected with malformed spermatozoa. Quality of spermatozoa of 19 subfertile men was significantly improved in terms of morphology and mobility after supplementation with 200 mg Pycnogenol for 90 days (23). Supplementation with Pycnogenol + L-arginine aspartate and vitamin E or testosterone improved dramatically motility, concentration, and quality of spermatozoa (R Stanislavov and V Nikolova, unpublished results).

Cognitive Function in the Elderly

A double-blind placebo-controlled study with healthy volunteer elderly participants (aged 60–85 years) who were not cognitively impaired found a significant

improvement of memory-based cognitive variables after three months treatment with 150 mg Pycnogenol a day (21). The authors found a correlation of memory improvement with decreased plasma F2-isoprostanes, metabolites developing from oxidized membrane lipids.

Attention-Deficit/Hyperactivity Disorder in Children

ADHD symptoms were shown to significantly decrease during treatment with Pycnogenol (1 mg/kg body weight) after one-month treatment, as compared to a placebo group (24). Symptoms were evaluated independently by parents and teachers using Connor's rating scale. One month after cessation a complete relapse of symptoms was found. The authors attribute the reduced ADHD symptoms to the anti-oxidant effect of Pycnogenol (22), but also point to decreased stress hormone levels of adrenaline and noradrenaline (25).

Circulatory Function

Improved Endothelial Function

Endothelium-dependent vasodilatation was investigated in healthy volunteers in double-blind placebo-controlled fashion (26). Forearm blood flow was evaluated by strain-gauge plethysmography following injection of acetylcholine. After consumption of 180 mg Pycnogenol daily for two weeks, vasodilatation significantly augmented forearm blood flow as compared to placebo. Administration of N^G -monomethyl-L-arginine, an e-NOS inhibitor, completely abolished the Pycnogenol[®]-induced augmentation of forearm blood flow response to acetylcholine, suggesting that Pycnogenol[®] improves endothelial function with increased NO production.

Improved Microcirculation

By microscopic observation of blood capillaries through fingernails it was found that the capillary diameter was increased significantly compared to placebo following intake of Pycnogenol. Supplementation of 60 cardiovascular patients with the extract for one month improved microcirculation significantly as a result of increased vasodilatation. The rate of cardiovascular events diminished significantly in the Pycnogenol group compared to placebo (2).

Antihypertensive Effect

In a double-blind placebo-controlled crossover study with 11 patients, supplementation with Pycnogenol lowered systolic blood pressure of patients from average 140 to 133 mm Hg and lowered thromboxane levels (27). In another double-blind placebo-controlled trial with 58 subjects, intake of 100 mg allowed to reduce significantly the dosage of the calcium channel blocker nifedipine, required for treatment of patients with hypertension. Plasma levels of endothelin-1 were reduced, and concentrations of prostacyclin were elevated (28). In a study of hypertensive type II diabetes patients on ACE-inhibitor medication, the intake of Pycnogenol over an investigational period of three months allowed 58.3% of patients to achieve a systolic blood pressure below 130 mm Hg. Half of the patients were able to reach healthy blood pressure with decreased ACE-inhibitor treatment when taking Pycnogenol. An unpublished study with hypotensive subjects (systolic pressure $\geq 90 \leq 115$ mm Hg) showed

that intake of 100 mg Pycnogenol daily over a period of 30 days did not significantly lower blood pressure (Daniel Pella MD, PhD.; written personal communication, 2005).

Muscular Cramps

Pycnogenol was described to help individuals suffering from common muscular cramps and pain. These individuals, as well as a group of athletes, suffered muscular cramps as a result of circulatory disorders related either to venous insufficiency, intermittent claudication, or diabetes (29). In all groups, 200 mg Pycnogenol taken a day for a period of four weeks significantly lowered the frequency of cramps and pain severity on a visual analog scale. Discontinuation for one week led to a partial relapse of symptoms without reaching pretreatment severity.

Inhibition of Platelet Aggregation

Smoking produces an activation and aggregation of blood platelets. This platelet aggregation was inhibited in smokers dose dependently by Pycnogenol (2), and the effect persisted over several days. In another group of smokers, thromboxane levels were decreased in blood in addition to the inhibition of platelet aggregation (2). Also, in cardiovascular patients, platelet aggregation was inhibited following intake of the extract (2).

Prevention of Thrombosis

In a double-blind, placebo-controlled, randomized trial with 198 passengers, 400 mg Pycnogenol prevented thrombus formation after long-haul flights in the verum group. In the placebo group, five cases of thrombosis were observed, and none in the verum group (30).

Cholesterol Lowering

In an open controlled study with 25 volunteers, LDL was lowered significantly after four weeks supplementation with 150 mg Pycnogenol, while high-density lipoprotein (HDL) as well as overall radical absorbance capacity of blood was increased (19). A double-blind placebo-controlled study with 21 patients showed significant reduction of total cholesterol and LDL after intake of 120 mg Pycnogenol (20). In a comparative controlled study, total cholesterol and LDL were significantly lowered (31).

Capillary Integrity

Gingival Bleeding

In a placebo-controlled study with dental students, a Pycnogenol-containing chewing gum (5 mg per piece) reduced gingival bleeding and plaque formation compared to regular sugar-free chewing gum (32).

Diabetic Retinopathy

Diabetic microangiopathy causes leakage of retinal capillaries. Two open-case experiments, two double-blind, placebo-controlled trials, and a multicenter field study, the latter with 1169 patients showed unequivocally that Pycnogenol in dosages of 20 to 160 mg a day retained progression of retinopathy and partly improved visual acuity. It restored capillary integrity and reduced leakage of blood into the retina (33).

An investigation of early stage retinopathy characterized by retinal edema with less pronounced bleedings showed that Pycnogenol (150 mg a day) significantly

improves retinal edema and visual acuity during three months treatment (34).

Inhibition of Edema Formation

Chronic venous insufficiency is associated with edema formation in the lower legs, leading to the feeling of heavy legs, swelling, cramps, and pain. Pycnogenol was described to improve venous microangiopathy in patients with severe chronic venous insufficiency. Skin microcirculation increased and capillary filtration decreased after eight weeks of treatment (35). Transcutaneous respiration was found to be improved as judged by decreased PCO_2 and increased PO_2 .

In five placebo-controlled, double-blind studies and three double-blind, controlled experiments, these symptoms were significantly reduced (2). Findings could be objectivated by measuring the circumference of lower limbs (31) and demonstrated superior activity compared to a commercial horse chestnut seed extract, a remedy for venous disorders (31). A comparative study of Pycnogenol versus a commercially available diosmin/hesperidin combination showed that Pycnogenol counteracted edema and symptoms significantly faster and was more pronounced (36). Another study compared the efficacy of troxerutin alone with a combination of troxerutin and Pycnogenol for relieving symptoms of chronic venous insufficiency. The combination was more effective for improving edema and symptoms and after discontinuation less relapse of symptoms occurred (37). Pycnogenol was shown to lower edema occurring as side effect in hypertensive patients medicated with nifedipine or ACE inhibitors (38). In healthy travelers on international flights, the intake of Pycnogenol prior to departure counteracted the development of ankle swellings (39).

The healing process of venous ulcers was found to be significantly accelerated with Pycnogenol as compared to an untreated control group (40). Skin microcirculation as well as transcutaneous respiration was found to be improved.

Jetlag Symptoms

Pycnogenol (150 mg/day for one week) was found to decrease typical jetlag symptoms when taken two days prior to departure for intercontinental travel (41). Symptoms such as fatigue, headache, disorientation, nausea, insomnia, and irritability were found to be less frequent and less pronounced than in an untreated control group. CT scans of passengers were found to show subliminal brain edema after arrival, which were less pronounced in the Pycnogenol-treated group.

Hemorrhoids

Pycnogenol has been investigated in a trial for patients with acute hemorrhoids (42). Within less than 48 hours after an acute attack, patients were treated with Pycnogenol that was found to significantly counteract bleedings, pain, and further symptoms as compared to a placebo-treated group. A third group received both oral and topical Pycnogenol that was more effective than oral treatment alone.

Anti-inflammatory Activity

Human Pharmacologic Investigations

Peripheral blood monocytes derived from healthy subjects before and after supplementation with Pycnogenol (200 mg daily for five days) were investigated to elucidate anti-inflammatory mechanisms (43). Ex vivo stimulation of monocytes in the presence of volunteers blood serum showed a decreased activation of key inflammatory mediator NF- κ B by in average 15%. A linear correlation between NF- κ B inhibition and release of matrix metalloproteinase-9 (MMP-9) was found. MMP-9 expression is well known to be one of many proteins under control of NF- κ B.

Another human pharmacologic study was carried out investigating neutrophils from humans who took 150 mg Pycnogenol for five days (44). Following ex vivo stimulation, expression of cyclooxygenase-2 (COX-2) and 5-lipoxygenase (5-LOX) was significantly inhibited as judged by real-time PCR, when volunteers had taken Pycnogenol.

Treatment of Osteoarthritis

Pycnogenol has been investigated in three clinical studies for lowering pain and improving flexibility in patients with mild to moderate osteoarthritis. The Western Ontario McMasters Questionnaire (WOMAC) was employed in these studies for evaluating the improvement of symptoms. Pycnogenol gradually improved pain, joint stiffness, and joint function scores, respectively, from one month to the next until completion of three months. Pain scores decreased by 43%, 40%, and 55%, respectively, after three months treatment in these studies (45–47). All three studies found that patients required significantly less pain management with nonsteroidal anti-inflammatory drugs (NSAIDs) when taking Pycnogenol, while this was not the case in the respective placebo-control groups. One of the three studies with 156 patients pointed to a better mobility of patients as judged from their walking distance on a treadmill, which increased from baseline average 68 m to 198 m after three months treatment with Pycnogenol. In that study, a subset of patients presented with elevated serum C-reactive protein levels at baseline, which was found to be significantly decreased from average 3.9 to 1.1 mg/L after three months treatment with Pycnogenol.

Improvements of Dysmenorrhea

Initial exploratory trials found that administration of 30 to 60 mg Pycnogenol helped women suffering from menstrual pain in dysmenorrhea and endometriosis (2). Supplementation with 60 mg Pycnogenol reduced intake of analgesics, number of days with pain, and intensity of low back pain and abdominal pain in 42 women suffering from menstrual pain (48). A multicenter field study showed that women taking Pycnogenol for two months required significantly less NSAID analgesic medication than a placebo-treated group. Interestingly, cessation of Pycnogenol intake for one month did not lead to a relapse to higher analgesic intake (49).

Pycnogenol was shown to gradually decrease pain in endometriosis over an investigation period of 48 weeks. On a visual analog scale, the average pain of 32 women

decreased from severe to moderate and five women got pregnant (50).

Reduction of Asthma Symptoms

The anti-inflammatory effects of Pycnogenol also contribute to its beneficial action on asthma patients. In a placebo-controlled, double-blind, crossover study, asthma symptom scores of 22 patients were significantly lower and lung function parameters higher in the Pycnogenol-treated group, while leukotriene levels decreased (2). In a double-blind placebo-controlled study with 60 children, the extract improved pulmonary function and asthma symptoms and reduced use of rescue inhalations. Leukotriene levels in urine were significantly lowered (51).

Inhibition of UV-Induced Inflammation

Oral intake of Pycnogenol lowers the inflammatory response to UV radiation. The minimum erythema doses were significantly increased after intake of 1.11 mg/kg body weight of Pycnogenol for four weeks in 21 healthy volunteers and further enhanced after a larger dose of 1.66 mg/kg likewise for four weeks (2). In a study with 30 women, taking 75 mg Pycnogenol for one month (52), the UV-induced discoloration of sun-exposed skin areas, melasma, could be reduced with respect to size of the affected area and intensity of discoloration.

Decrease of Side Effects in Cancer Chemotherapy and Radiotherapy

In a pilot trial, a daily dosage of 150 mg Pycnogenol was taken by cancer patients during their course of chemoradiotherapy (53). Pycnogenol was found to decrease the incidence and severity of a broad range of symptoms to some extent, as compared to a control group taking placebo.

Anti-diabetic Effects

In patients with freshly diagnosed type II diabetes, Pycnogenol was found to dose dependently lower both fasting and postprandial blood glucose levels (54). A dosage of 50 mg Pycnogenol significantly lowered postprandial blood glucose, no effect was found on insulin levels. The effect is suggested to result from α -glucosidase inhibition by large-chain procyanidins (55).

Results were confirmed in a placebo-controlled double-blind study with type II diabetic patients on medication with metformin and sulfonylurea (56). Pycnogenol taken in addition to antidiabetic medication significantly further lowered fasting blood glucose and, furthermore, decreased endothelin-1 and increased prostacyclin. Another double-blind placebo-controlled study with type II diabetic patients confirmed significant reduction of fasting glucose and HbA_{1c} levels in patients receiving metformin, sulfonylurea, thiazolidinediones, or combinations of these (57). Moreover, 125 mg Pycnogenol a day significantly lowered systolic blood pressure in these hypertensive diabetic patients who were medicated with ACE inhibitors. This study found significantly decreased urinary albumin.

Pycnogenol was found to improve signs and symptoms of diabetic microangiopathy (58). Microcirculation

of the lower legs in patients with diabetic ulcers was increased and capillary filtration decreased in response to four weeks treatment with 150 mg Pycnogenol a day. Pycnogenol improves the healing process of diabetic ulcers, which coincides with increased transcutaneous PO₂ and decreased PCO₂ (59).

Efficacy

Pycnogenol has demonstrated anti-edema effect in several clinical studies as well as efficacy in inhibiting the progression of retinopathy. Other clinical investigations support the application of the extract to protect the circulation by inhibition of platelet aggregation, lowering of cholesterol, and an antihypertensive effect. An enhanced radical absorbing capacity after intake of Pycnogenol is probably related to protection against UV radiation and inflammatory diseases. The anti-diabetic effect and anti-spasmodic activity has to be confirmed by further clinical and mechanistic studies.

Optimum Intake

Clinical studies suggest an optimum dose range between 40 and 100 mg Pycnogenol/day or 1 mg/kg body weight. Pycnogenol should be taken together with breakfast to minimize gastrointestinal troubles.

Side Effects

The evaluation of clinical studies with more than 7000 patients to date (end of year 2009) revealed no serious adverse events related to intake of Pycnogenol. The rate of mild side effects is low, and unwanted effects, such as gastrointestinal troubles, dizziness, nausea, headache, or skin sensations were mild and transient in most cases.

Contraindications

To date, no contraindications have been seen.

Observed Drug Interactions

No drug interactions have been reported until now.

Use in Pregnancy and for Children

Despite the fact that teratogenicity tests showed no teratogenic effects, the intake of Pycnogenol during the first three months of pregnancy and during breast feeding should be avoided as a general precaution. Children younger than 12 years should not take Pycnogenol because no clinical experience is available with young children.

REGULATORY STATUS

In most countries, for example, in the United States, Australia, the United Kingdom, Belgium, the Netherlands, Finland, Italy, Thailand, Taiwan, P.R. China, and Japan, Pycnogenol is used as a food supplement. In the United States, Pycnogenol has the status of GRAS. In Greece, Switzerland, Colombia, and Venezuela, it is a nonprescriptional herbal drug.

Garcinia

Frank Greenway

INTRODUCTION

Garcinia cambogia is the Latin name for a plant that bears the tamarind fruit and thrives on the Indian subcontinent and in western Sri Lanka. The dried rind of the tamarind fruit, Malabar tamarind, contains (–)-hydroxycitric acid (HCA), the one isomer of citric acid that inhibits adenosine triphosphate (ATP) citrate oxaloacetate lyase (EC 4.1.3.8) (CLy) also known as citrate lyase or citrate cleavage enzyme. Inhibition of this enzyme limits the generation of acetyl CoA, which is needed for fatty acid and cholesterol synthesis. HCA reduces food intake and causes weight and fat loss in rodents. It has also been a component of dietary herbal supplements for the treatment of obesity. The results of human trials have been mixed. This appears to be due to the bioavailability of HCA varying according to its method of preparation. This chapter will examine the safety and efficacy of *G. cambogia* for weight loss through animal trials, clinical trials, and case reports.

BACKGROUND

Garcinia is from the family called Guttiferae, which is a large genus of polygamous trees or shrubs distributed in tropical Asia, Africa, and Polynesia. Garcinia consists of 180 species, of which 30 are found in India. An isomer of citric acid, HCA, is found in the fruit rinds of three species of Garcinia: *cambogia*, *indica*, and *atroviridis*. These species thrive prolifically on the Indian subcontinent and in western Sri Lanka.

G. cambogia is a small or medium-sized tree with a rounded crown and horizontal or drooping branches. The leaves are dark green, elliptical, and shiny, 2 to 5 in. long and 1 to 3 in. broad. The fruits are ovoid, red, or yellow when ripe, contain six to eight seeds and are 2 in. in diameter with six to eight grooves. The tree is found in evergreen forests up to an altitude of 6000 ft. It flowers during the hot season and the fruits ripen during the rainy season.

G. indica is a slender evergreen tree with drooping branches and ovate leaves 2.5 to 3.5 in. long and 1 to 1.5 in. broad. The fruit is dark purple and has five to eight seeds. It flowers in November to February and the fruits ripen in April to May. *G. atroviridis* is a moderate-sized graceful tree growing 30 to 50 ft high with leaves that are 6 to 9 in. long and 2 to 3 in. broad. Its fruits are orange-yellow, 3 to 4 in. across and fluted.

The fruits of *G. cambogia* are too acidic to be eaten raw. A tea made from this fruit has been used in folk

medicine for rheumatism, bowel complaints, and in veterinary medicine to treat mouth pathology in cattle. The fruit of *G. indica* has an agreeable flavor and a sweet acidic taste. It is used as a garnish to give an acidic flavor to curries and for preparing syrups in the summer months. The fruit has also been used in folk medicine as a treatment for parasitic worms, dysentery, hemorrhoids, tumors, pain, and heart complaints. The dried rinds of both species are used to flavor curries. The fruit rinds of *G. atroviridis* are stewed with sugar and eaten or used as a sour relish in curries and as a dressing for fish (1).

The dried rind of the fruit of *G. cambogia* is known as Malabar tamarind and is used extensively for culinary purposes and commercially for Columbo curing of fish. It contains 30% citric acid as dry weight and acts like a pickling media with bacteriostatic properties due to its low pH. In fact, this curing process has been shown to prevent the formation of histamine in dark meat fish, such as skipjack, and prevent scombroid fish poisoning (2).

More recently, other uses of *G. cambogia* fruit have been explored. In experiments that screened for dose-dependent tumoricidal effects of a wide variety of natural extracts using an immortalized neuroblastoma cell line of spontaneous malignant origin, *G. cambogia* was found to have tumoricidal activity (3). Garcinol and guttiferone K isolated from *G. cambogia* were shown to protect lipids and proteins from oxidation (4). An extract from the fruit rind of *G. cambogia* was shown to improve the histology of Crohn disease and ulcerative colitis in rodents (5). Attempts have been made to isolate the bioactive components that may be responsible for these effects, but more work is needed. The fresh biomass of *G. cambogia* has been demonstrated to remove trivalent arsenic from contaminated ground water and has the capability of being reused for five cycles (6). Despite these potential uses of *G. cambogia*, the predominant use commercially has been in dietary supplements to treat obesity. The rest of this chapter will concentrate on the use of the extract from the rind of *G. cambogia* and its active component HCA for the treatment of obesity.

CHEMISTRY AND PREPARATION

HCA, one of the isomers of citric acid, was shown by Watson and Lowenstein in the late 1960s to be an inhibitor of the extra mitochondrial enzyme, CLy (7). Aqueous extractions of the fruit rind from *G. cambogia* contain both HCA and its lactone. When the extract is saponified with excess alkali and passed through an ion exchange resin it

Figure 1 Structures of hydroxycitric acid isomers. Source: From Ref. 1.

is converted to its free HCA but, by concentrating the water extract, all of the HCA is converted to the lactone. One method of isolating HCA from the *G. cambogia* involves extracting the dried fruit rinds with ether, evaporating the ether to give the lactone, and passing the lactone through an anion exchange column to recover HCA after elution with sodium and potassium hydroxide.

Citric acid has four carbon atoms, so it has two isomers around each of the inside carbons for a total of four isomers (Fig. 1). Free acid leads to the formation of HCA lactone during concentration and evaporation due to its hygroscopic nature (Fig. 2). Thus, for commercial purposes, stable derivatives have been prepared using the lactone and the sodium, potassium, or calcium salts. All the original animal studies were performed by using the sodium salt.

HCA was demonstrated to be the only isomer of citric acid to competitively inhibit CLy, and the salt of HCA was shown to be much more active than its lactone. CLy exists in the cell outside the mitochondria. Inside the mitochondria, acetyl CoA, water, and oxaloacetate form citrate and CoA. The citrate crosses the mitochondrial membrane and enters the cytoplasm of the cell. In the cytoplasm of the cell outside of the mitochondria, citrate plus ATP plus CoA

Figure 2 Structures of hydroxycitric acid lactones. Source: From Ref. 1.

form acetyl CoA and oxaloacetate. The acetyl CoA formed in this manner forms the basis for fatty acid and cholesterol synthesis (Fig. 3). Thus, by inhibiting CLy, HCA inhibits the synthesis of cholesterol and fatty acids. Inhibition of cholesterol and triglyceride synthesis by HCA has been suggested as a treatment for hyperlipidemia, since the elevation of triglycerides in obesity is driven by an increased production of very low-density lipoproteins in the liver. Triglycerides in rodents treated with HCA were decreased by 20% and cholesterol was reduced by 30% compared to controls. HCA not only depresses lipogenic rates in the liver, fat, and intestine, but also decreases food intake, reduces body weight, and body fat without reducing body protein levels (8). This reduction in body weight in rodents treated with HCA was entirely driven by the reduction in food intake, as demonstrated by a similar reduction of body weight in pair-fed controls (9). The reduction in food intake by HCA did not seem to be due to conditioned aversions.

PRECLINICAL STUDIES

Studies with 3T3L1 cells, murine preadipocytes, treated with HCA showed that lipid accumulation and the differentiation of preadipocytes was inhibited (10). A gene expression study demonstrated that HCA increased the RNA expression of genes involved in lipolysis while decreasing those involved in the differentiation of fat cells (11). A gene expression study also revealed an upregulation of genes expressing the serotonin receptor in the abdominal fat cells of rats (12). In a study using rat cortical slices, serotonin reuptake was inhibited and serotonin availability was increased in a manner similar to that seen with serotonin reuptake inhibitors, which are known to affect body weight (13). Three tests for genotoxicity were performed with HCA—a bacterial reverse mutation assay (Ames test), an in vitro chromosomal aberration test, and an in vivo micronucleus test. Only the in vivo micronucleus test showed any abnormalities (14), and it demonstrated a dose-dependent increase in micronucleated polychromatic erythrocytes per thousand polychromatic erythrocytes. Although this test showed that HCA preferentially induced micronuclei, another study using the same assay gave a normal result (15).

The original studies showing body fat reduction in rats without a reduction in body protein, a reduction in triglyceride synthesis, a reduction in cholesterol synthesis, a reduction of serum levels of cholesterol and triglyceride, in addition to a reduction in food intake were performed using the sodium salt of HCA. Most of the recent studies with HCA have not been specific regarding the exact composition of the HCA (the lactone, a monovalent salt, or a divalent salt) making interpretation of the results of these studies more difficult.

There were three preclinical studies, using *G. cambogia*, performed in mice that bear mentioning. One demonstrated that *G. cambogia* extract reduced visceral adiposity (16). Another showed that *G. cambogia* reduced insulin and insulin resistance (17). The third study showed that mice-fed chow containing 10% by weight of sucrose and 3.3% as an herbal extract of *G. cambogia* showed no skin pathology over four weeks (18). A rat study using

Figure 3 Mechanism of action of (7)-hydroxycitric acid [(7)-HCA] on fatty acid (FA) metabolism. (7)-HCA is a strong allosteric competitor of citrate, decreasing the formation of cytosolic acetyl coenzyme A (CoA). The decreased availability of acetyl CoA would lead to a reduced formation of malonyl CoA which, in turn, would stimulate the activity of carnitine transferase (CAT), the enzyme responsible for the transfer of fats back into the mitochondria for oxidation. Insulin indirectly makes CAT more sensitive to inhibition by malonyl CoA, whereas glucagon activates CAT and promotes lipolysis. Source: From Ref. 39.

G. cambogia deserves mention as well. Rats given dexamethasone 10 mg/kg/day or dexamethasone with *G. cambogia* fruit extract 1 g/kg/day for eight days were compared in terms of their serum lipids. The *G. cambogia* extract blocked the rise in LDL cholesterol and very low-density lipoprotein (VLDL) triglycerides seen with dexamethasone in the control rats (19). In addition to rodents, *G. cambogia* has been shown to reduce fat mass in cats as well (20).

The other preclinical studies used HCA. Mice were treated with 10 mg of HCA or a water control for 25 days. Free fatty acid levels were significantly higher, glycogen content of the gastrocnemius muscle was higher, maximal swimming time to fatigue was longer, and the respiratory quotient was lower at the end of the study in the HCA group showing that HCA promotes lipid oxidation and spares carbohydrate utilization at rest and during exercise compared to the untreated control group (21). A study in rats demonstrated that HCA stimulated erythropoiesis in addition to promoting weight loss (22). Another study in rats showed that HCA reduced the respiratory quotient (RQ) (23). Rats that lost weight on food restriction regained weight at a slower rate when treated with HCA compared to rats in the control group (24). A study of a commercial calcium and potassium salt of HCA mixed in a 1:1 ratio reduced food intake and attenuated inflammation, oxidative stress, and insulin resistance in Zucker rats compared to controls (25). The same calcium-potassium salt mixture of HCA reduced body weight, triglycerides, cholesterol, and increased high-density lipoprotein (HDL) cholesterol (25).

Safety studies were also carried out using the same calcium-potassium salt mixture. In studies lasting 90 days, rats were treated with up to 5% of their diet with a product that was 60% potassium salt and 40% calcium salt of HCA. The expected reduction in body weight and food intake was observed, but there was no hepatic DNA fragmentation, no difference in hematology testing, clinical chem-

istry testing, or histopathological findings. In addition, there was no change in testicular lipid peroxidation (26). Another study in Zucker rats showed testicular pathology in those rats treated with high doses of a different HCA preparation (27). The no adverse effect level in the study that demonstrated testicular toxicity was 389 mg of HCA per kilogram of body weight per day that is equivalent of 6 g/day in an obese human and above the doses sold for weight loss. The study showing testicular atrophy has not been repeated.

CLINICAL STUDIES

Manufacturers of dietary herbal supplements often combine several supplements in one product. This makes determining very difficult which component of the supplement may be responsible for the effects seen in a trial. For that reason, this review will concentrate on studies that look at *G. cambogia* or HCA in isolation or with a minimum of additional ingredients.

All the original animal studies conducted by the Roche Pharmaceutical company used sodium salt of HCA. Due to the hygroscopic nature of the sodium salt and the tendency of HCA to form a lactone, which is ineffective in inhibiting citrate cleavage enzyme, the original commercial forms of HCA were made from the calcium salt that is more stable. Since the calcium salt is poorly bioavailable, the products that are now being sold usually contain the potassium salt or a combination of the potassium salt with the calcium salt. Louter-van de Haar et al. (28) performed an interesting study in which they compared three products—the first was 97% potassium salt, the second was 50% potassium salt, and the third was a 1:1 mixture of a potassium and a calcium salt (Fig. 4). As one might expect, the rodents receiving these products by gavage had the greatest reduction in food intake caused by the product containing almost entirely the potassium salt, and almost

Figure 4 Structures of hydroxycitric acid derivatives. Source: From Ref. 1.

no food intake reduction with the mixture containing the potassium and calcium salts, with the lower concentration potassium salt alone in between the other two in decreasing food intake. These findings are consistent with the larger doses of the potassium and calcium salts needed to achieve blood levels and efficacy in clinical trials. It also is consistent with the lack of efficacy of some of the earlier clinical trials that were performed at a time when most of the commercial products were made entirely with the calcium salt. Unfortunately, the papers describing HCA studies often do not describe the form of HCA they used. The form of HCA used in the clinical trials to be described in this section will be included when available, since the

form of HCA may explain the divergent results seen in the various clinical trials (Table 1).

Although the doses of HCA in the clinical studies vary widely from 110 to 4400 mg/day, most of the studies report a significant weight loss compared to placebo in studies lasting from 2 to 12 weeks. The study by Heymsfield et al. (29) did not show weight loss, and it was one of the longer and larger studies in addition to being well designed. This study did not confirm that blood levels of HCA increased during administration of the oral supplement. At the time this study was performed, most of the commercial products used the calcium salt of HCA. Thus, it is possible that some, if not all, of the negative

studies of HCA may be due to the poor bioavailability of the calcium salt. Although, like with weight loss, the results of different studies conflict, HCA has been shown in clinical trials to reduce LDL cholesterol, triglycerides, and raise HDL cholesterol. Food intake and appetite have been reduced with HCA, and HCA decreased de novo lipogenesis. HCA increases exercise time to exhaustion, spares glycogen, and increases fat oxidation in trained athletes as well as in untrained men and women.

Moreover, two safety studies in humans bear mentioning. Due to the concern raised by the study in Zucker rats cited earlier that demonstrated testicular toxicity, Hayamizu et al. explored the effect of 1000 mg/day of HCA over 12 weeks in 44 men and women on serum testosterone, estrone, and estradiol. No significant effects were seen (45). Another study evaluated electrocardiograms in 20 healthy volunteers given a commercial product, Metabolife 356 ephedra-free, which contained *G. cambogia* in unspecified amounts in addition to a large number of other dietary herbal supplement ingredients. The QTc and other electrocardiographic variables were measured over five hours with no evidence of any toxicity (46). The safety of Super CitriMax[®], a potassium and calcium salt of HCA, was reviewed (47). The animal studies cited were reviewed earlier in the preclinical section. Several placebo-controlled double-blind trials using up to 2800 mg/day of HCA were cited with no adverse events reported. The authors concluded that animal and human data support the safety of HCA in humans up to a level of 2800 mg/day.

Several case reports document adverse events in participants taking products containing HCA. Many, if not most, commercial dietary herbal supplement products containing *G. cambogia* or HCA contain many other ingredients as well. This, of course, makes interpreting these case reports more difficult. One case report describes a 54-year-old woman who developed rhabdomyolysis with a peak creatine phosphokinase (CPK) of 1028 IU/L three hours after taking a dietary herbal supplement. Her chest pain lasted two hours and did not return with discontinuation of the supplement. The supplement contained ephedra, guarana, chitosan, *Gymnema sylvestre*, and *G. cambogia*. This case report, since it is the only one referencing rhabdomyolysis, is less concerning than those reporting hepatotoxicity of which there are several reports.

Two subjects taking Hydroxycut, a product made by MuscleTech in Ontario, Canada, were the subjects of a case report describing severe hepatotoxicity. Both subjects were healthy males between 25 and 30 years of age. One had a cholestatic picture with an alkaline phosphatase over 500 U/L, a bilirubin of 7.8 mg/dL, and a liver biopsy showing cholestasis. The other subject had liver enzymes in the 4000 to 6000 U/L range and a bilirubin of 7.8 mg/dL suggesting a more hepatitic picture. Hydroxycut contains *G. cambogia*, *Gymnema sylvestre*, glucomannan, α -lipoic acid, willow bark extract, L-carnitine, green tea extract, and guarana extract. Four other cases of reversible hepatic toxicity in healthy people between the age of 20 to 40 years taking Hydroxycut were also reported. A 45-year-old asthma patient being treated with montelukast was reported to die of liver failure and was taking supplements containing *G. cambogia* among many other ingredients. Due to the association of liver toxicity with Hydroxycut,

it was postulated that *G. cambogia* extract was playing a role, but montelukast has also been associated with hepatic failure. Since animal toxicity studies do not support a role for *G. cambogia* in hepatic toxicity, and since the cases of hepatic toxicity seem to be primarily associated with Hydroxycut, it seems likely that the Hydroxycut product may have contained a hepatotoxic contaminant. Since dietary herbal supplements are considered to be foods, the burden of proof that a supplement is toxic or unsafe rests with the Food and Drug Administration (FDA) in contrast to drugs where proof of safety is the responsibility of the pharmaceutical manufacturer. Case reports with no denominator are not convincing proof of toxicity when no similar findings are seen in controlled clinical trials. When the FDA has attempted to restrict dietary herbal supplements due to concern about safety, their decisions have usually been overturned due to a lack of scientific proof showing toxicity. This was the case with ephedra until the most recent decision to declare ephedra as an adulterant, which was not challenged by industry.

MECHANISM OF ACTION

Pair feeding experiments in rodents demonstrated that a reduction in food intake was responsible for the weight loss seen with HCA treatment (9). Attention has been given to the mechanism by which HCA decreases food intake. It has been shown that HCA inhibits the synthesis of fatty acids in the brain, and it has been postulated that this might have a role in signaling food intake. HCA has also been shown to release serotonin from cortical brain slices of a rat, and an increase in central serotonin has been associated with weight loss. HCA also limits acetyl CoA availability for the synthesis of acetylcholine, and this, too, has been postulated to alter the control of food intake. Removing the afferent fibers from the subdiaphragmatic vagus nerve did not block the anorectic effect of HCA, suggesting that the reduction in food intake was not mediated by vagal afferents. The increase of glycogen storage in the liver and muscle has been pointed out as another possible explanation for the decrease in food intake, but Hellerstein and Xie (48) demonstrated that neither hepatic glycogen nor hexose phosphates were involved in the food intake suppression. It appears that the most likely explanation for the reduction in food intake is the reduction of malonyl CoA caused by the lack of acetyl CoA substrate from HCA inhibition of CLy. The reduction in malonyl CoA removes the suppression of carnitine palmitoyl transferase 1 (CPT 1) by malonyl CoA, which would result in stimulating fat oxidation. HCA appears to act peripherally, since there are negligible amounts of HCA in the brains of treated rats, and HCA suppresses food intake in rodents with ventral medial hypothalamic lesions. Recently, studies were performed with human preadipocytes differentiated in culture. The addition of a potassium and calcium salt of HCA increased lipolysis induced by isoproterenol and by iso-butyl-methylxanthine. HCA also induced leptin expression and dispersed fat droplets suggesting an increase in lipolysis. Of 54,676 genes screened, 348 were downregulated and 366 were upregulated by HCA. This gene expression work supports the antiadipogenic properties of HCA and generates hypotheses regarding the

mechanism of action of HCA that can be explored in future research (49).

REGULATORY STATUS

The rinds from the *G. cambogia* fruit have a long history of use in foods in India. They are used in folk medicine, to preserve fish, and to flavor curries and syrups. Thus, *G. cambogia* is recognized as a food product. The discovery that *G. cambogia* extract contains high levels of HCA that inhibits CLy and reduces food intake led to its use in dietary herbal supplements for the treatment of obesity. Dietary herbal supplements are also considered food from a regulatory perspective in the United States.

SUMMARY AND CONCLUSIONS

The rinds of the *G. cambogia* fruit have a long history of culinary use in India to flavor curries, preserve fish, and for use in folk medicine. In the late 1960s, HCA, one of the four isomers of citric acid, was found to be in abundance in the rind of the *G. cambogia* fruit, and it was discovered that this isomer uniquely inhibits CLy. CLy is the first step in fatty acid synthesis outside the mitochondrion. Inhibiting this enzyme reduces the supply of acetyl CoA and reduces malonyl CoA production. This removes the inhibition on CPT1 and may be a mechanism by which HCA decreases appetite. The reduction in food intake by HCA is responsible for its reduction in body weight, but other mechanisms like the increase in serotonin that has been demonstrated may also be involved in the mechanism of the food intake reduction. Studies of gene transcription have shown a variety of genes that are differentially regulated by HCA and these findings may suggest further research into the mechanisms by which HCA reduces food intake.

Preclinical data suggest that the use of HCA is safe at very high levels and it consistently demonstrates weight loss with a reduction in cholesterol and triglycerides. Preclinical studies also show a reduction in visceral fat, a reduction in insulin resistance, an increase in exercise time to exhaustion, an increase in fat oxidation, and a sparing of carbohydrate substrate during exercise. One study raised a concern about testicular damage from high dose HCA, but this finding has not been replicated. Clinical studies are much less consistent, but one can find studies supporting the preclinical findings. Safety concerns were raised about liver toxicity, but this appears to be due to a single product and may be due to a contaminant in the manufacturing process.

In conclusion, an extract from the rinds of the *G. cambogia* fruit contains a specific isomer of citric acid, HCA, which inhibits CLy, reduces food intake, and causes weight loss in animal and man. The preclinical and clinical studies suggest that the extracts made from *G. cambogia* fruit rinds have a wide margin of safety. It now appears that the monovalent salts of HCA are most effective in causing weight loss, reducing cholesterol and triglycerides, increasing exercise endurance, and increasing fat oxidation during exercise. The confusion regarding the efficacy of *G. cambogia* extract in the treatment of obesity

appears to be due to the poor bioavailability or poor inhibition of CLy by the lactone of HCA or its divalent calcium salt. This suggests that future trials should consider using the monovalent salts of HCA acid.

Garlic

J. A. Milner

INTRODUCTION

Garlic (*Allium sativum*) is revered throughout the world as part of a healthful diet (1,2). Reference to garlic was made about 5000 years ago in Egyptian and Indian writings. According to early transcripts from Egypt, Greece, Rome, China, and India, garlic was prescribed for multiple medical purposes, including treatment of infections, improved physical performance, and protection against toxins. These medicinal attributes, coupled with its savory characteristics, have made garlic a true cultural icon. This chapter provides a critical synopsis of the evidence relating garlic to health and how its source, quantity, and duration of exposure can influence the body's response.

USAGE

Garlic is not simply a spice, herb, or vegetable but a combination of all three, which translates to its use in various ways in meal preparations. It is a member of the Alliaceae family of plants and thus has characteristics similar to those of onions, leeks, and chives (Fig. 1). This family has over 2500 species, pointing to its size and diversity.

Knowledge about garlic's intake is qualitative, rather than quantitative, because it is not traditionally considered in dietary assessment surveys. Therefore, consumption patterns must be viewed with caution because personal preferences, and therefore intakes, vary considerably. Nevertheless, consumption patterns are recognized to vary from region to region and from individual to individual within region (3,4). According to United States Department of Agriculture (USDA) reports in the late 1990s, approximately 18% of Americans consume at least one food containing garlic on a typical day, which is comparable to the consumption pattern of foods such as French fries (16%) (5). Garlic also continues to be one of the top-selling dietary supplements in the United States and in several other parts of the world. In 2008, according to Information Resources, Inc., the top-selling herbal singles in the food, drug, and mass-market channels were cranberry (*Vaccinium macrocarpon*), soy (*Glycine max*), garlic (*A. sativum*), saw palmetto (*Serenoa repens*), and ginkgo (*Ginkgo biloba*).

Knowledge about garlic usage is typically qualitative, rather than quantitative, because it is not traditionally monitored by dietary assessment surveys, and standardized databases for the many varieties of garlic and supplement preparations are not readily available. Regardless, its average intake in the United States has been estimated to

Figure 1 Garlic has been revered for its medicinal properties for centuries, as evident by ancient writings from Egypt, Greece, China, and India. Today 300 to 400 varieties of garlic cultivated worldwide. While garlic is more than a source of sulfur, a variety of compounds that may promote health are known to arise when it is peeled and crushed.

be approximately 0.6 g/wk or less (3), whereas in some parts of China, it may be as much as 20 g/day (4,6). Average intakes may have limited meaning because personal preferences, and therefore usage, can vary considerably. It is not clear whether the response is dose dependent, although there is evidence from China suggesting that a reduction in prostate cancer risk occurs in subjects consuming higher amounts (>10 g/day) of garlic compared with those consuming less (≤ 2.2 g/day) (7). While several biological processes may respond to garlic, it remains unclear who benefits, what factors determine the magnitude of the response, and the minimum quantity and duration needed to bring about a response.

Claims about the health benefits of garlic likely contributed to its clinical usage, especially by individuals flirting with alternative health care strategies. Peng et al. (8) found that approximately 43% of veteran outpatients were taking at least one dietary supplement along with

Table 1 Structures of Some Biologically Active Lipid- and Water-Compounds Isolated from Garlic

Chemical	Structure
Allicin	$\text{CH}_2=\text{CH}-\text{CH}_2-\overset{\text{O}^-}{\underset{ }{\text{S}^+}}-\text{CH}_2-\text{CH}=\text{CH}_2$
Ajoene	$\text{CH}_2=\text{CH}-\text{CH}_2-\overset{\text{O}^-}{\underset{ }{\text{S}^+}}-\text{CH}_2-\text{CH}=\text{CH}-\text{S}-\text{S}-\text{CH}_2-\text{CH}=\text{CH}_2$
Diallyl sulfide (DAS)	$\text{CH}_2=\text{CH}-\text{CH}_2-\text{S}-\text{CH}_2-\text{CH}=\text{CH}_2$
Diallyl disulfide (DADS)	$\text{CH}_2=\text{CH}-\text{CH}_2-\text{S}-\text{S}-\text{CH}_2-\text{CH}=\text{CH}_2$
Diallyl trisulfide (DATS)	$\text{CH}_2=\text{CH}-\text{CH}_2-\text{S}-\text{S}-\text{S}-\text{CH}_2-\text{CH}=\text{CH}_2$
(S)-Allylcysteine (SAC)	$\text{CH}_2=\text{CH}-\text{CH}_2-\text{S}-\text{CH}_2-\overset{\text{NH}_2}{\underset{ }{\text{CH}}}-\text{COOH}$
(S)-Allylmercaptocysteine (SAMC)	$\text{CH}_2=\text{CH}-\text{CH}_2-\text{S}-\text{S}-\text{CH}_2-\overset{\text{NH}_2}{\underset{ }{\text{CH}}}-\text{COOH}$

their prescription medication(s). Several botanicals are commonly consumed by patients with cancer and include black cohosh, Echinacea, garlic, ginkgo, green tea, kava, milk thistle, and St John's wort (9). Adusumilli et al. (10) found that approximately 57% of patients undergoing elective surgery had used herbal medicine at some point in their life. Echinacea, aloe vera, ginseng, garlic, and ginkgo were among the most common. Interestingly, in this study, one in six patients used herbal supplements during the month of surgery. Stys et al. (11) reported that patients with a history of myocardial infarction, coronary revascularization, and hyperlipidemia and a family history of coronary artery disease were more likely to use supplements, including multivitamins, vitamin E, vitamin C, vitamin B, folate, garlic, calcium, coenzyme Q10, and ginkgo, than were those without comparable health concerns.

While some individuals tolerate rather large quantities of garlic, for example, 20 g/day, some may not be as tolerant (12–14). A spectrum of adverse reactions has been observed, admittedly rather infrequently, including contact dermatitis, respiratory distress, gastrointestinal disturbances, bleeding abnormalities, and anaphylactic shock. The dearth of case reports highlighting these events points to the low frequency but also that complications can occur as a result of garlic over indulgence.

CHEMISTRY OF GARLIC

Garlic's distinctive characteristics arise from sulfur, which constitutes almost 1% of its dry weight (15). While garlic does not typically serve as a major source of essential nutrients, it may contribute to several dietary factors with potential health benefits. While carbohydrates constitute only approximately 33% of garlic's weight, there are a significant proportion of oligosaccharides, which may influence gastrointestinal flora or gastrointestinal function (16,17). While garlic has a moderate amount of protein, it is a relatively rich source of the amino acid arginine. Antioxidant properties associated with carbohydrate-arginine polymers may contribute to some of garlic's proposed health benefits (18). The presence of several other constituents, including selenium and

flavonoids, may influence the magnitude of the body's response to garlic (19–21).

Most studies about garlic constituents focus on its sulfur components (22–24) (Table 1). The primary sulfur-containing constituents in garlic bulbs are γ -glutamyl-(S)-alk(en)yl-L-cysteines and (S)-alk(en)yl-L-cysteine sulfoxides. Considerable variation in (S)-alk(en)ylcysteine sulfoxide content of garlic has been reported, ranging between 0.53% and 1.3% of the fresh weight, with allicin [(S)-allylcysteine sulfoxide] being the largest contributor (22). Allicin concentrations can increase during storage because of the transformation of γ -glutamyl-L-cysteines. In addition to allicin, garlic bulbs contain small amounts of (+)-(S)-methyl-L-cysteine sulfoxide (methiin) and (+)-(S)-(trans-1-propenyl)-L-cysteine sulfoxide, (S)-(2-carboxypropyl)glutathione, γ -glutamyl-(S)-allyl-L-cysteine, γ -glutamyl-(S)-(trans-1-propenyl)-L-cysteine, and γ -glutamyl-(S)-allyl-mercapto-L-cysteine (4,15,22–24).

Allicin is the major thiosulfinate compound (allyl-2-propenethiosulfinate or diallyl thiosulfinate) occurring in garlic and its aqueous extracts. When garlic is chopped or crushed, allinase enzyme, present in garlic, is activated and acts on alliin (found in the intact garlic) to produce allicin [thio-2-propene-1-sulfinic acid (S)-allyl ester]. Because allicin is relatively unstable, it further decomposes to sulfides, ajoene, and dithiins (24,25). Garlic's characteristic odor arises largely from allicin and its oil-soluble metabolites. Heating garlic is associated with a denaturing of allinase and a reduction in allyl mercaptan, methyl mercaptan, and allyl methyl sulfide. The decreased formation of these metabolites is associated with a reduction in smell (25) and with its anticarcinogenic potential (26). Overall, the method used to process garlic can dramatically influence the sulfur compounds that predominate and its biological response (4,26,27).

While the pharmacokinetics of allyl sulfur compounds within mammals has not been adequately examined, it is unlikely that allicin occurs in a significant proportion once garlic is consumed. If it does, the liver should quickly transform it to diallyl disulfide (DADS) and allyl mercaptan (28). Germain et al. (29) provided evidence that DADS is absorbed and transformed into allyl mercaptan, allyl methyl sulfide, allyl methyl sulfoxide, and

allyl methyl sulfone. Thus, hosts of compounds likely arise from ingestion of the parent compounds found in garlic. While allyl methyl sulfone predominated in tissues, both the sulfoxide and the sulfone have been identified in urine (29).

IMPLICATIONS IN HEALTH PROMOTION

Garlic has been reported to alter several physiological processes that may influence health, including those associated with heart disease and cancer (30–34). While these results generally support earlier views about garlic's medicinal properties, the clinical findings pointing to the potential benefits of garlic are often mixed, suggesting that not all individuals will respond identically, if at all, or that there are inadequate clinical studies to make firm recommendations about the quantity or duration needed to bring about a response. The strength of the evidence can also be inadequate. Such is the case for the relationship between garlic intake and the proposed reduced occurrence of the common cold, which appears to rely largely on poor-quality evidence (35). Nevertheless, scientists, legislators, and consumers worldwide continue to be intrigued with garlic's potential health benefits. This passion may come from the mounting, and rather compelling, preclinical evidence that points to the influence of garlic and its related sulfur components on a host of biological processes associated with health (21).

Some of the health benefits attributed to the consumption of garlic and its associated allyl sulfur components are

- Antibacterial
- Antifungal
- Antiviral
- Anticarcinogenic
- Antioxidant
- Anti-inflammatory
- Antithrombotic

Antimicrobial Effects and Cancer Prevention

Historical documents reveal that garlic has been used for centuries to preserve foods (36,37). Garlic extracts have been demonstrated to suppress the proliferation of microbes including *Salmonella*, *Escherichia coli* O157:H7, and *Listeria*. Lee et al. (38) found that garlic is very active against a spectrum of pathogens, including clinical antibiotic-resistant strains such as methicillin-resistant *Staphylococcus aureus* (MRSA), methicillin-resistant *Staphylococcus epidermidis*, vancomycin-resistant enterococci, and ciprofloxacin-resistant *Pseudomonas aeruginosa*. Most recently, it was found that the antibacterial activity of allicin was completely eliminated by cysteine, glutathione, and coenzyme A but not by non-SH-compounds. The oxygen in the structure ($-S(=O)-S-$) of allicin therefore functions to liberate the (S)-allyl moiety, which might be an offensive tool against bacteria (39).

Chronic bacterial prostatitis is a relatively common cause of relapsing urinary tract infections in men. Sohn et al. (40), in a rat model, examined the antimicrobial and anti-inflammatory effects of garlic [9 mg of garlic concentrate per kilogram of body weight (Uiseong

nonghyup, Uiseong, South Korea) diluted in 1 mL of distilled water and administered through an oral gavage twice a day for three weeks] in the presence or absence of ciprofloxacin on chronic bacterial (*E. coli* Z17, O2:K1:H–)-induced prostatitis. The garlic group showed decreased bacterial growth and reduced prostatic inflammation compared with the control group. Furthermore, the use of garlic plus ciprofloxacin showed a significant decrease in bacterial growth as well as improvement in prostatic health compared with the use of ciprofloxacin alone. These results suggest that garlic can work in concert with other antimicrobial/anti-inflammatory agents.

Garlic and its components can also serve as potent antifungal agents (41). Lemar et al. (42) reported that fresh garlic extract was more effective in retarding *Candida albicans* than was a garlic powder extract. The antiyeast activity of garlic oil appears to be relative stable. Incorporating the allyl sulfur compounds in nanoparticles enhances their antifungal properties (43). Most recently, Ledezma and Apitz-Castro (44) suggested that ajoene might be one of the most potent allyl sulfur compounds in garlic that has antifungal properties.

It should be noted that all microbes are not equally sensitive to garlic or its constituents. Sivam et al. (45) reported that while 40 µg of thiosulfinate per milliliter inhibited *Helicobacter pylori*, it did not influence *S. aureus*. Nevertheless, it should also be noted that in some cases the garlic extract was more effective than classical antibiotics (36). At this point, it is unclear what accounts for the variation in antimicrobial response, although differences in uptake and/or metabolism of the bioactive component are most likely involved, and therefore source of the preparation becomes an important determinant of the response.

In addition to allicin, compounds including diallyl sulfide (DAS), DADS, (E)-ajoene, (Z)-ajoene, (E)-4,5,9-trithiadeca-1,6-diene-9-oxide [(E)-10-devinylajoene, (E)-10-DA], and (E)-4,5,9-trithiadeca-1,7-diene-9-oxide [iso-(E)-10-devinylajoene, iso-(E)-10-DA] have been reported to influence microbial growth (46–48). Although there are clear differences in the efficiency with which these compounds alter proliferation, relatively small amounts appear to be effective deterrents. The target(s) accounting for the antimicrobial effects of allyl sulfur compounds remain to be determined. However, it is logical to assume that the response reflects alterations in membrane protein sulfhydryls and/or a change in the redox state. Support for this comes from studies showing that allyl sulfur compounds can influence the fluidity of cellular membranes (49).

Heating is recognized to blunt the antimicrobial effectiveness of garlic, suggesting that alliin breakdown is needed to bring about a response. Lee et al. (38) found that cooked garlic and commercial garlic pills exhibited no antimicrobial activity against a spectrum of pathogens, again suggesting that alliinase inactivation prevents the formation of the actual active component. Thus, it will not be surprising that garlic preparations vary in their antimicrobial properties. Unfortunately, because most preparations are not standardized to an active component or to a biological/biomarker response, it is impossible to draw firm conclusions about commercial preparations in the marketplace. Likewise, because few clinical studies have examined the antimicrobial response to garlic or its specific allyl sulfides, it is difficult to draw firm conclusions

about the physiological significance of findings in this area, although the results are tantalizing.

Coronary Effects of Garlic

Garlic has received considerable attention for its possible cardiovascular benefits (30–32). While a number of studies have reported that garlic lowers cholesterol and several other factors linked with heart disease, numerous inconsistencies in the literature are also noted. It is certainly possible that garlic may influence the genesis and progression of cardiovascular disease through several biological effects including a decrease in total and low-density lipoprotein (LDL) cholesterol, an increase in high-density lipoprotein (HDL) cholesterol, a reduction in serum triglyceride and fibrinogen concentrations, a lowered arterial blood pressure, and/or an inhibited platelet aggregation. A recent meta-analysis (50) revealed that garlic therapy did not produce any statistically significant reduction in serum total cholesterol level (mean difference: -0.04 mmol/L, 95% CI: -0.15 to 0.07 mmol/L), LDL-cholesterol level (mean difference: 0.01 mmol/L, 95% CI: -0.10 to 0.11 mmol/L), triglycerides level (mean difference: -0.05 mmol/L, 95% CI: -0.17 to 0.06 mmol/L), or apolipoprotein B level (mean difference: -0.02 g/L, 95% CI: -0.03 to 0.001 g/L), although moderate-to-high heterogeneity was noted (50). The contradictory results may be due to several factors, including a lack of consistency in the dosage of garlic employed, the standardization of garlic preparations in terms of active component(s), and the duration of intervention and the degree of insult (variation in degree of hypercholesterolemia). The large variation in the quantity of garlic used, that is, 7 to 28 cloves/day, makes direct comparisons difficult. Several years ago, Thomson and Ali (51) reported that consuming 3 g of fresh garlic daily for 16 weeks decreased blood cholesterol by approximately 21%. Because a significant decrease was not detected before four weeks, there may be minimal exposure time before a response occurs. Thus, not only quantity but also duration of exposure must be considered when evaluating results from garlic intervention studies.

In a recent meta-analysis (52) involving 29 trials, garlic was correlated with significantly reduced total cholesterol (-0.04 ; 95% CI: -0.15 to -0.07 mmol/L) and triglyceride levels (-0.05 ; 95% CI: -0.17 to -0.06 mmol/L) but did not significantly affect LDL or HDL levels. Again, it is unclear how important quantity and duration are in determining the outcome.

LDL oxidation is recognized as one of several factors involved with the initiation and progression of atherosclerosis (53). Oxidation of LDL occurs when exposed to free radicals released by surrounding cells, such as smooth muscles cells, or monocytes/macrophages, both of which might be influenced by garlic intake (54). Several years ago, Munday et al. (55) provided evidence that oxidation of LDL particles by Cu^{2+} from subjects was reduced in subjects given 2.4 g aged garlic extract (AGE) daily for seven days compared with those who did not receive the supplement. A similar response was not observed when subjects were given raw garlic (6 g), suggesting that not all preparations are comparable in bringing about a physiological change. Most recently, Ou et al. (56) compared the abilities of four allyl sulfur compounds (DAS, DADS,

(S)-ethylcysteine, *N*-acetylcysteine) for their ability to alter LDL oxidation. While all were found effective, there were clear differences in their efficacy. It should be noted that water-soluble allyl sulfur compounds such as those found in deodorized preparations have also been reported to reduce LDL oxidation (57). Overall, it is unclear whether the literature discrepancies about garlic and LDL oxidation relate to the subjects examined, the preparations used, and/or the quantity and duration of exposure.

The uptake of oxidized LDL (ox-LDL) by vascular endothelial cells is recognized as a critical step in the initiation and development of atherosclerosis. Adhesion molecules are known to be upregulated by ox-LDL and numerous inflammatory cytokines likely play a pivotal role in the overall response. Recently, Lei et al. (58) demonstrated that DAS, DADS, and DATS (diallyl trisulfide) reduced adhesion molecule expression induced by ox-LDL and cell surface expression of (*E*)-selectin and vascular cell adhesion molecule 1 (VCAM-1). The protein kinase A (PKA) inhibitor H89 reversed the suppression of VCAM-1 by DADS and DATS, but the phosphoinositide 3-kinase (PI3K) inhibitor wortmannin had no effect. In contrast, wortmannin abolished DADS- and DATS-induced suppression of ox-LDL-induced (*E*)-selectin expression. These results suggest that the suppression of ox-LDL-induced (*E*)-selectin and VCAM-1 expression by DADS and DATS, and thus monocyte adhesion to endothelial cells, is likely dependent on the PI3K/PKB or PKA/CREB signaling pathway in an adhesion molecule-specific manner.

Aortic stiffening is another risk factor in cardiovascular morbidity and mortality. This stiffness coincides with a high systolic blood pressure and augmented pulse pressure. Reuter et al. (59) provided evidence that garlic reduced blood pressure, increased fibrinolytic activity, and inhibited platelet aggregation in humans. These findings are supported recently by findings in the rabbit that garlic can reduce atherosclerotic plaque (60). However, Isaacsohn et al. (61) using another garlic preparation (Kwai) found no change in blood pressure. The dearth of studies, coupled with the wide variation in experimental designs, makes it virtually impossible to evaluate garlic as a modifier of blood pressure (62). Interpreting results with inadequate study designs, methodological deficiencies with few details about blood pressure measurement, makes meta-analysis of questionable value. Furthermore, the particular insult (systolic or diastolic) may be a decisive factor in determining the response because a meta-analysis suggests that those with elevated systolic blood pressure are more responsive to garlic (63).

Preclinical evidence does suggest that a reduction in blood pressure is plausible. Specifically, using a Goldblatt model for hypertension, Al-Qattan et al. (64) reported that garlic was effective in exerting a sustained depression in arterial blood pressure possibly by regulating sodium homeostasis. Garlic treatment has also been found to lead to a dose-dependent vasorelaxation in both endothelium-intact and mechanically endothelium-disrupted pulmonary arterial rings *in vitro* mode (65). The likelihood that the response depends on nitric oxide (NO) synthase activity was suggested by the ability of NG-nitro-L-arginine methyl ester, a NO synthase inhibitor, to block the vasorelaxation.

The ability of garlic to influence blood NO concentrations in human beings was recently examined (66). Ingesting 2 g fresh, but not boiled, garlic was found to increase the basal plasma level of NO from 2.7 to 8.8 μ M. Interestingly, basal plasma IFN- α level increased from 9.5 to 46.3 nM. Thus, consumption of garlic appears to stimulate synthesis of NO and, in turn, IFN- α in humans.

The influence of garlic on NO status appears to relate to reducing the complications associated with a biological insult. Allicin and ajoene have been reported to cause a dose-dependent inhibition of the iNOS (inducible nitric oxide synthase) system in lipopolysaccharide (LPS)-stimulated RAW 264.7 macrophages (67). iNOS is recognized to occur in human atherosclerotic lesions and is thought to promote the formation of peroxynitrites. Evidence exists that allicin may inhibit iNOS activity through a dose-dependent decrease in iNOS mRNA levels and by reducing arginine transport through a downregulation of CAT-2 mRNA (68). Kim et al. (69) provide evidence that both garlic extracts and (S)-allyl cysteine have similar behaviors in reducing iNOS and NO concentrations in macrophages and endothelial cells.

Acute coronary syndromes can occur when an unstable atherosclerotic plaque erodes or ruptures, thereby exposing the highly thrombogenic material inside the plaque to the circulating blood (70). This exposure triggers a rapid formation of a thrombus that occludes the artery. Campbell et al. (71) noted that feeding a deodorized garlic preparation (Kyolic) reduced the fatty streak development and vessel wall cholesterol accumulation in rabbits fed a cholesterol-fortified diet. Similarly, garlic consumption for 48 weeks in a randomized trial was found to reduce arteriosclerotic plaque volumes in both the carotid and femoral arteries by 5% to 18% (72). Experiments by Siegel et al. (73) prove evidence that garlic extracts can inhibit Ca^{2+} binding to heparan sulfate proteoglycan. Because the ternary proteoglycan receptor/LDL cholesterol/calcium complex is critical for the "nanoplaque" composition, and ultimately for the arteriosclerotic plaque, the observed reduction caused by garlic provides a biological basis for why some individuals may benefit more than others.

Aggregates of activated platelets also likely have a pivotal role in coronary syndromes. Garlic and some of its organosulfur components have been found to be potent inhibitors of platelet aggregation (74). Boiling garlic retards its ability to inhibit platelet aggregation, again suggesting allyl sulfur compounds likely need to be formed by alliin lyase (alliinase) action (75). Induction of aggregation also influences the response to garlic. Hiyasat et al. (76) found that garlic extracts inhibited platelet aggregation induced via the adenosine diphosphate (ADP) pathway and to a lesser extent aggregation induced by epinephrine, whereas arachidonic acid- and collagen-induced aggregation was not affected. Unfortunately, few studies have documented that garlic can modify platelet aggregation in vivo. Several years ago, Steiner and Li (77) provided evidence that consumption of AGE in humans reduced epinephrine- and collagen-induced platelet aggregation, although it failed to influence ADP-induced aggregation. Their studies also provided evidence that platelet adhesion to fibrinogen could be suppressed by consumption of this garlic supplement. It should be noted

that the effectiveness of allyl sulfur compounds tends to disappear rapidly, suggesting that genetic differences in its metabolism/catabolism may determine overall response.

Overall, garlic's ability to reduce hyperlipidemia, hypertension, and thrombus formation under some circumstances makes it a likely candidate for lowering the risk of heart disease and stroke. Undeniably, the enormous variability observed in the literature indicates that global benefits are unlikely. It remains unclear why these discrepancies exist, but total exposures, genetics, and the degree of abnormality are likely key variables. Additional studies will surely clarify who might benefit most from added garlic more than social intake.

Influence on Multiple Tissues and Processes Related to Cancer

Preclinical models provide rather compelling evidence that garlic and its associated components can reduce the incidence of breast, colon, skin, uterine, esophagus, and lung cancers (21,33,78,79). However, evidence in human investigations is less compelling (34). *It is unclear whether the varied diet of humans or the quantity of garlic typically consumed accounts for differences between human and animal investigations.* The ability of garlic to inhibit tumors arising from different inducing agents and in different tissues indicates that a generalized cellular event is likely responsible for the change in tumor incidence and that the response is highly dependent on environmental or other types of biological insults. Fluctuations in several processes associated with cancer, including carcinogen formation, carcinogen bioactivation, DNA repair, tumor cell proliferation, and/or apoptosis, may account for these observations (Fig. 2). It is likely that several of these processes are modified simultaneously. Their specificity in terms of the dose of allyl sulfur needed to bring about a response

Figure 2 The anticancer benefits ascribed to garlic may relate to alterations in one or more processes. Each of these processes has been reported to be altered by one or more allyl sulfur compounds that occur in processed garlic. Garlic is sometimes referred to as the stinking rose because of its benefits often being linked to one or more of its sulfur compounds it can supply.

and the temporality of the change needed to bring about a phenotypic change needs additional clarification.

Nitrosamine Formation and Metabolism

Suppressed nitrosamine formation continues to surface as one of the most likely mechanisms by which garlic may block cancer. Several studies (21) suggest that allyl sulfur compounds can retard the spontaneous and bacterial-mediated formation of nitrosamines. Because many of the nitrosamines are considered suspect carcinogens in various tissues, this block may be particularly important. Dion et al. (36) demonstrated that not all allyl sulfur compounds were equal in retarding nitrosamine formation. The ability of (S)-allyl cysteine (SAC) and its non-allyl analog (S)-propyl cysteine to retard NOC formation, but not DADS, DPDS (dipropyl disulfide), and DAS, reveals the critical role that the cysteine residue plays in the inhibition. However, lipid-soluble allyl sulfur compounds are effective in retarding microbial growth and thus may indirectly influence the formation of nitrosamines.

The reduction in nitrosamine formation may arise secondarily to increase the formation of nitrosothiols. Williams (80) suggested, almost 20 years ago, that several sulfur compounds might reduce nitrite availability for nitrosamine formation by enhancing the formation of nitrosothiols. Because the allyl sulfur content among garlic preparations can vary enormously, it is reasonable that not all commercial preparations will be equivalent in their ability to retard nitrosamine formation. While S-nitrosylation is known to influence health and disease, it is unclear how garlic influences this process across various cell types.

Some of the most compelling evidence that garlic depresses nitrosamine formation in humans comes from studies by Mei et al. (81). Their studies demonstrated that ingesting 5 g of garlic per day blocked the enhanced urinary excretion of nitrosoproline resulting from exaggerated nitrate and proline intake. Most recent evidence suggests that as little as 1 g of garlic may be sufficient to suppress nitrosoproline formation (82). The significance of this observation comes from the predictive value that nitrosoproline has as an indicator for the synthesis of other potential carcinogenic nitrosamines (83).

The anticancer benefits attributed to garlic are also associated with suppressed nitrosamine bioactivation. Evidence from multiple sources point to the effectiveness of garlic to block DNA alkylation, an initial step in nitrosamine carcinogenesis (84,85). In agreement with this reduction in bioactivation, Dion et al. [46] reported that both water-soluble (S)-allyl sulfide and lipid-soluble DADS retarded nitrosomorpholine mutagenicity in *Salmonella typhimurium* TA100. Aqueous garlic extracts have also been shown to reduce the mutagenicity of ionizing radiation, peroxides, Adriamycin, and *N*-methyl-*N'*-nitro-nitrosoguanidine (86).

A block in nitrosamine bioactivation may arise from inactivation of cytochrome P450 2E1 (CYP2E1) (87,88). An autocatalytic destruction of CYP2E1 may account for some of the chemoprotective effects of DAS and possibly other allyl sulfur compounds against nitrosamine carcinogenesis (88). Fluctuations in the content and overall activity of P450 2E1 may be a key variable in determining the mag-

nitude of the protection provided by garlic and associated allyl sulfur components.

Bioactivation and Response to Other Carcinogens

Garlic and several of its allyl sulfur compounds can also effectively block the bioactivation and carcinogenicity of a host of carcinogenic compounds (21). This protection, which traverses a diverse array of compounds and cancers occurring in several tissues, again suggests an overarching biological response. Because metabolic activation is required for many of these carcinogens, there is likelihood that either phase I or II enzymes are altered (89,90). Interestingly, little change in cytochrome P-450 1A1, 1A2, 2B1, or 3A4 activities has been detected following treatment with garlic or related sulfur compounds. However, this lack of responsiveness may relate to the quantity and duration of exposure, the quantity of carcinogen administered, or the methods used to assess cytochrome content or activity. Wu et al. (91), using immunoblot assays, found that the protein content of cytochrome P450 1A1, 2B1, and 3A1 was increased by garlic oil and each of several isolated disulfide compounds. Their data demonstrated that the number of sulfur atoms in the allyl compound is inversely proportional to the depression in these cytochromes. Thus, phase I enzyme activity changes may account for some of the anticancer properties attributed to garlic.

Changes in bioactivation resulting from a block in cyclooxygenase and lipoxygenase may also partially account for the reduction in chemically induced tumors (92). Ajoene has been shown to interfere with the COX-2 pathway in LPS-activated RAW 264.7 cells (93). While limited, there is also evidence that garlic and associated sulfur components can inhibit lipoxygenase activity (94,95). Collectively, these studies pose interesting questions about the role of both cyclooxygenase and lipoxygenase in not only forming prostaglandins, and therefore modulating tumor cell proliferation and immunocompetence, but also their involvement in the bioactivation of carcinogens. Additional attention is needed to clarify what role, if any, these bioactivation enzymes have in determining the biological response to dietary garlic and its allyl sulfur components.

Detoxification and Allyl Sulfur Specificity

Increased activity of several detoxification enzymes, including NAD(P)H:quinone oxidoreductase and glutathione (S)-transferase (GST), may also partially account for the experimental anticancer properties provided by garlic (96). Not all GST isozymes are influenced equally by organosulfur compounds (97). Bose et al. (98) demonstrated that mGSTP1 mRNA expression was either unaltered in liver or moderately increased in forestomach following treatment with DPDS, indicating that the allyl group is critical for the mGSTP1-inducing activity of DADS. The induction of GST also depends on the presence of the enhancer element GPE I (99). Electromobility gel shift assay have revealed that the DADS and DATS induction of GST is accompanied by a concentration-dependent increase in DNA-binding activity of nuclear activator protein-1 (AP-1). The phosphorylation of c-Jun NH2-terminal kinase (JNK) and extracellular signal-regulated kinase (ERK), but not of p38, was also stimulated in the

presence of both garlic allyl sulfides. Pretreatment with JNK and ERK inhibitors prevented the increase in AP-1-DNA-binding activity and also the induction of GSTP protein by either allyl sulfide. These results indicate that the effectiveness of DADS and DATS on GSTP expression is likely related to the JNK-AP-1 and ERK-AP-1 signaling pathways and, thus, that DADS and DATS enhance the binding of AP-1 to GPE I (99).

Rarely have water- and oil-soluble allyl sulfur compounds been compared within the same study. Nevertheless, available evidence suggests that major differences in efficacy among extracts are not of paramount importance, at least for blocking the initiation phase of carcinogenesis (100). While subtle differences among garlic preparations are likely to occur, quantity, rather than source, appears to be a key factor influencing the degree of protection. Differences that do occur between preparations likely relate to the content and effectiveness of individual sulfur compounds. Nevertheless, the number of sulfur atoms present in the molecule seems to influence the degree of protection, in the order DATS > DADS > DAS (101). Likewise, the presence of the allyl group generally enhances protection over that provided by the propyl moiety (98,102).

Cell Proliferation and Apoptosis

Several lipid- and water-soluble organosulfur compounds have been examined for their antiproliferative efficacy (21,32,103). Some of the more commonly used lipid-soluble allyl sulfur compounds in tumorigenesis research are ajoene, DAS, DADS, and DATS. A breakdown of allicin appears to be necessary for achieving maximum tumor inhibition. Previous studies reported that lipid-soluble DAS, DADS, and DATS (100 μ M) were more effective in suppressing canine tumor cell proliferation than isomolar water-soluble SAC, (S)-ethyl cysteine, and (S)-propyl cysteine (103). While treating human colon tumor cells (HCT-15) with 100 μ M DADS completely blocks growth, approximately 200 μ M SAMC [(S)-allylmercaptocysteine] is required to lead to a similar depression (104). No changes in growth were observed with concentrations of SAC up to 500 μ M. Undeniably, not all allyl sulfur compounds from garlic are equally effective in retarding tumor proliferation. While the quantities used in the investigations are relatively high, these do appear to be close to what might happen with more physiological garlic intake.

Evidence exists that these allyl sulfur compounds preferentially suppress neoplastic over nonneoplastic cells. Adding DATS (10 μ M) in vitro to cultures of A549 lung tumor cells inhibited their proliferation by 47%, whereas it did not influence nonneoplastic MRC-5 lung cells (101). The antiproliferative effects of allyl sulfides are generally reversible, assuming that apoptosis has not occurred (104). Similarly, Kim et al. (105) found not only that DATS triggers mitochondria-mediated apoptosis program in human prostate cancer cells (LNCaP, LNCaP-C81, LNCaP-C4-2) irrespective of their androgen responsiveness and also that a normal prostate epithelial cell (PrEC) line was significantly more resistant to apoptosis induction.

SAMC, DAS, and DADS have also been reported to increase the percentage of cells blocked within the G₂/M phase (106,107). p34(cdc2) kinase is a complex that governs the progression of cells from the G₂ into the M phase

of the cell cycle. Activation of this complex promotes chromosomal condensation and cytoskeletal reorganization through the phosphorylation of multiple substrates, including histone H1. The G₂/M phase arrest induced by DADS has been found to coincide with the suppression in p34(cdc2) kinase activity (106). DADS appears to inhibit p34(cdc2) kinase activation through a decrease in the p34(cdc2)/cyclin B(1) complex and modest change in p34(cdc2) hyperphosphorylation (106). Using LNCaP and HCT-116 human cancer cells, Xiao et al. (107) demonstrated that checkpoint kinase 1-mediated mitotic arrest resulting from DATS is key to apoptosis induction. The G(2) arrest was accompanied by downregulation of cyclin-dependent kinase 1, cell division cycle (Cdc) 25B, and Cdc25C, leading to Tyr15 phosphorylation of Cdk1 (inactivation). The DATS-mediated mitotic arrest correlated with inactivation of anaphase-promoting complex/cyclosome as evidenced by accumulation of its substrates cyclinB1 and securin. Transfection with Chk1-targeted siRNA conferred significant protection against DATS-induced mitotic arrest (107).

Scavenging of DADS-induced reactive oxygen species (ROS) by N-acetyl cysteine or reduced glutathione has also been reported to inhibit cell cycle arrest, apoptosis, and p53 activation caused by DADS treatment (108). These results suggest that ROS trigger the DADS-induced cell cycle arrest and apoptosis and that ROS are involved in stress-induced signaling upstream of p53 activation. Transfecting p53 small interfering RNA prevented the accumulation of cleaved poly(ADP-ribose) polymerase and sub-G1 cell population by 65% and 35%, respectively. Moreover, DADS-induced apoptosis was prevented by treatment with oligomycin, known to prevent p53-dependent apoptosis by reducing ROS levels in mitochondria (108).

Several of the allyl sulfur compounds from garlic have also been reported to induce apoptosis (109,110). Activation of caspase-3 appears to be at least partially responsible for the induction of apoptosis (111,112). The induction of apoptosis DATS, and likely other allyl sulfur compounds, appears to relate to an induction of proapoptotic Bax protein and upregulation and relocation of p53 (110). Knockdown of Bax and Bak proteins conferred significant protection against DATS-induced apoptotic cytoplasmic histone-associated DNA fragmentation (113).

DADS has also been reported to inhibit the growth of Hras oncogene transformed tumors in nude mice (114), thus suggesting that other mechanisms may account for a reduction in tumor proliferation and increase in apoptosis. Allicin has been reported to induce activation of extracellular signal-regulated kinases 1 and 2 (ERK1/2) in human peripheral mononuclear cells and also in wild-type Jurkat T-cells (115). Allicin failed to activate ERK1/2 in Jurkat T cells that express p21(ras), in which Cys118 was replaced by Ser. Because these cells are not susceptible to redox-stress modification and activation, the authors suggested that immunomodulation may be involved with the redox-sensitive signaling such as activation of p21(ras) (115).

Cell Differentiation and Angiogenesis

Lea et al. (116) suggest that at least part of the ability of DADS to induce differentiation in DS19 mouse

erythroleukemic cells relates to its ability to increase histone acetylation. DADS caused a marked increase in the acetylation of H4 and H3 histones in DS19 and K562 human leukemic cells, and more recently in HL 60 cells (117). Allyl mercaptan is a particularly potent inhibitor of histone deacetylase (HDAC) (118). Histone deacetylase inhibition has the potential to derepress epigenetically silenced genes in cancer cells, leading to cell cycle arrest and apoptosis. Interestingly, DADS inhibition of HDAC has also been reported to be sufficient to stimulate adipogenesis (119). Dashwood and colleagues have screened several garlic-derived small organosulfur compounds for their ability to inhibit HDAC activity in vitro (118,120). Chromatin immunoprecipitation assays identified hyperacetylated histone H3 on the P21WAF1 gene promoter within four hours after allyl mercaptan exposure, which correlated with increased binding of the transcription factor Sp3 (120). Their findings suggest a primary role for Sp3 in driving P21 gene expression after HDAC inhibition by allyl sulfur compounds and coincided with cell cycle arrest. In contrast to the effect on histone acetylation, there was a decrease in the incorporation of phosphate into histones when DS19 cells were incubated with 25 μ M (S)-allylmercaptocysteine (121).

Alliin has been reported to cause a dose-dependent inhibition of fibroblast growth factor-2 (FGF2)-induced human endothelial cell tube formation and angiogenesis in the chick chorioallantoic membrane (CAM) model (122). Both vitamins C and E significantly ($p < 0.001$) enhanced the inhibitory efficacy of alliin on angiogenesis (122). The water-soluble allyl compounds in AGEs have also been reported to inhibit the growth of colorectal cancer cells and their angiogenic properties (123). Xiao et al. (124) suggest that the antiangiogenic characteristics of DADS relate to its ability to downregulate vascular endothelial growth factor (VEGF) secretion and VEGF receptor-2 protein level and inactivation of Akt kinase.

Dietary Modifiers of Garlic and Allyl Sulfur Efficacy

The influence of garlic on the cancer process cannot be considered in isolation, because several dietary components and the intake of drugs can markedly influence its overall impact (40,92,125,126). Garlic may enhance the pharmacological effect of anticoagulants (e.g., warfarin, flutindione) and reduce the efficacy of anti-AIDS drugs (i.e., saquinavir), although it is difficult to predict how important these interactions truly are for the general public (127,128). Among the dietary factors recognized to influence the response to garlic are total fat, selenium, methionine, and vitamin A (125). Selenium, supplied either as a component of the diet or as a constituent of the garlic, has been reported to enhance the protection against 7,12 dimethylbenz(a)anthracene mammary carcinogenesis over that provided by garlic alone (125,129). Suppression in carcinogen bioactivation, as indicated by a reduction in DNA adducts, may partially account for this combined benefit of garlic and selenium; both selenium and allyl sulfur compounds are recognized to alter cell proliferation and induce apoptosis. Other food components bring about enhanced efficacy by reducing the amounts of allyl sulfur required to bring about a response or by influencing

an additional molecular target and thereby bringing about a synergist response.

SUMMARY AND CONCLUSIONS

Garlic is a plant within the genus *Allium* that appears to have multiple characteristics that may significantly promote health and disease prevention. While it is possible that all allium foods possess similar health benefits, there is a dearth of comparative studies. Because garlic has few side effects, there are few disadvantages associated with its enhanced use, except for its lingering odor. However, odor does not appear to be a prerequisite for many of the health benefits because preclinical studies indicate that water-soluble (S)-allyl cysteine (predominates in deodorized preparations) sometimes provides benefits comparable to those provided by compounds that are linked to odor. It is probable that garlic and its associated water- and lipid-allyl sulfur compounds influence multiple and key molecular targets associated with cancer prevention. While most can savor the culinary experiences identified with garlic, some individuals because of their gene profile and/or environmental exposures may be particularly responsive to more exaggerated intakes. While there continues to be considerable interest in the health benefits of garlic, the number of controlled clinical studies limits the conclusions that can be drawn. Likewise, the dearth of studies that have contrasted the importance of source and/or dose of specific garlic preparations makes interpretation of existing data particularly challenging. At this point, the most prudent advice may be to continue to enjoy the savory characteristics of garlic as frequently as possible.

Ginger

Tieraona Low Dog

INTRODUCTION

Ginger is a popular spice and its world production is estimated at 100,000 tons annually, of which 80% is grown in China (1). In addition to its long history of use as a spice, references to ginger as a medicinal agent can be found in ancient Chinese, Indian, Arabic, and Greco-Roman texts. Ginger has been used for a variety of conditions, but it is chiefly known as an antiemetic, anti-inflammatory, digestive aid, diaphoretic, and warming agent. In the year 2005, ginger sales ranked 20th among those of all herbal supplements sold in U.S. mainstream retail stores (2).

NAME AND GENERAL DESCRIPTION

The Zingiberaceae family consists of 49 genera and 1300 species, of which there are 80 to 90 species of *Zingiber* and 250 species of *Alpinia*. This entry will focus primarily upon the scraped or unscraped rhizome of common ginger, *Zingiber officinale* Roscoe, a reed-like plant grown in numerous subtropical areas of the world, including Jamaica, India, China, and Africa (3).

CONSTITUENTS

Ginger rhizome contains 4% to 10% oleoresin composed of nonvolatile, pungent constituents (phenols such as gingerols and their related dehydration products, shogaols); nonpungent fats and waxes; 1.0 to 3.3% volatile oils of which 30% to 70% are sesquiterpenes, mainly β -bisabolene, (–) zingiberene, β -sesquiphellandrene, and (+) arcurcumene; monoterpenes, mainly geranial and neral; 40 to 60% carbohydrates, mainly starch; 9 to 10% proteins and free amino acids; 6 to 10% lipids composed of triglycerides, phosphatidic acid, lecithins, and free fatty acids; vitamin A; niacin; and minerals (4).

Gingerols are the most abundant pungent compounds in fresh rhizome, the most abundant being 6-gingerol. Shogaols, the dehydrated form of gingerols, are present only in small quantities in the fresh rhizome and are mainly found in the dried and thermally treated roots, with 6-shogaol being the most abundant (5).

PHARMACOKINETICS

A clinical trial was conducted to evaluate the pharmacokinetic profile of 6-gingerol, 8-gingerol, 10-gingerol, and 6-shogaol and their conjugate metabolites at six-dose levels of ginger extract standardized to 5% gingerols, 100, 250,

500, 1000, 1500, and 2000 mg, administered orally to 27 healthy human volunteers (6). Researchers found that the main pungent constituents of ginger root, 6-gingerol, 8-gingerol, 10-gingerol, and 6-shogaol, are quickly absorbed and detected in the serum as glucuronide and sulfate conjugates, with the majority detected as glucuronide metabolites. These constituents, at concentrations normally found in ginger root (0.5%–2.5%), are detectable in the serum starting at a 1-g dose with the exception of 6-gingerol, which is detectable at a 250-mg dose with maximum concentrations ranging from 0.1 $\mu\text{g/mL}$ to 1.7 $\mu\text{g/mL}$. Ginger conjugates begin to appear 30 minutes after oral dosing, reaching their T_{max} between 45 to 120 minutes, with elimination half-lives ranging from 75 to 120 minutes at the 2-g dose.

As there are more clinical trials evaluating the effectiveness of ginger for a variety of conditions, pharmacokinetic studies using multidose modeling are essential to optimize dosing regimens and delivery systems.

PHARMACODYNAMICS

Antiemetic Activity

Numerous human clinical trials have addressed the antiemetic effects of dried ginger root in the treatment of hyperemesis gravidarum (7), motion sickness (8), postoperative nausea (9), and chemotherapy-induced nausea and vomiting (10). The mechanism of action and constituent(s) responsible for the antiemetic activity of ginger are not completely understood. A class of antiemetics found to be clinically effective in the treatment of chemotherapy-induced and postoperative nausea and vomiting are the 5-hydroxytryptamine (5-HT) antagonists, specifically 5-HT₃. Several components of ginger, viz., 6-gingerol, 6-shogaol, and galanolactone, have shown anti-5-HT activity in isolated guinea pig ileum. Galanolactone is a competitive antagonist predominantly at ileal 5-HT₃ receptors (11). A study in rats found that an acetone extract of ginger and ginger juice effectively reversed the cisplatin-induced delay in gastric emptying typically seen when the drug is administered. The reversal produced by the ginger acetone extract was similar to the effect seen with the 5-HT₃-receptor antagonist ondansetron; ginger juice, at doses of 2 and 4 mL/kg orally (p.o.) was superior to the drug (12). Other researchers have demonstrated that ginger increases gastrointestinal (GI) motility, reducing the feedback from the GI tract to central chemoreceptors (12), though a double-blind crossover trial of 16 healthy volunteers who were randomly allocated to receive either

1 g of dried ginger or placebo found no effect on gastric emptying (13).

Motion Sickness

Human studies evaluating the effects of ginger on experimentally induced motion sickness (14) and four human clinical trials evaluating the use of ginger for motion sickness have been published. The first randomized, double-blind, placebo-controlled study was published in 1988. Eighty Danish naval cadets (ages 16–19 yr) were randomized to receive either 1 g of dried ginger powder or placebo. Symptoms of seasickness were evaluated over the following four hours. Participants who received ginger powder experienced less seasickness than those in the control group ($P < 0.05$). No power calculation was included in the report.

A 1994 randomized, double-blind, nonplacebo-controlled study of 1475 volunteers (age 16–65 yr) traveling by sea compared the efficacy of seven antiemetic medications: Touristil[®] (cinnarizine 20 mg, clomperidone 15 mg), Marzine[®] (cyclizine 50 mg), Dramamine[®] (dimenhydrinate 50 mg, caffeine 50 mg), Permesin[®] (meclizine 25 mg, caffeine 20 mg), Stugeron[®] (cinnarizine 20 mg), Scopoderm TTS[®] (scopolamine 0.5 mg), and Zintona[®] (product standardized to minimum 1.4% volatile oils and minimum 2.0 mg gingerols and shogaols in capsule containing 250 mg ginger rhizome). Stugeron and Scopoderm TTS were administered the evening prior to departure, with a second dose of Stugeron being given the morning of sea travel. The other medications were administered 2 hour prior to departure, with Touristil and Zintona being administered again 4 hour later. None of the study medications offered complete protection from seasickness, with all offering similar rates of efficacy. In each treatment group, 4.1 to 10.2% experienced vomiting and 16.4 to 23.5% experienced nausea and discomfort. There was no statistical difference between groups. No serious adverse reactions were reported (15). Though interesting, the study did not include a baseline measurement of nausea/vomiting sensitivity.

A 1999 randomized, double-blind drug comparison study found the efficacy of ginger extract (Zintona) and dimenhydrinate to be similar when given to 60 cruise ship passengers (age 10–77 yr) with a history of motion sickness (16). Side effects were significantly less in the ginger group (13.3%) than in those receiving dimenhydrinate (40%). Comorbid conditions were not ruled out and no power calculation was included in the report.

Another 1999 randomized, double-blind study compared the efficacy of a ginger extract (Zintona) and dimenhydrinate in the pediatric population (17). Twenty-eight children, aged four to eight years, with a history of motion sickness as determined by questionnaire were enrolled in the trial. Fifteen subjects received ginger and 13 received dimenhydrinate. Subjects (3–6 yr) in the ginger group received 250 mg of ginger extract half an hour before the trip and, if necessary, 250 mg every 4 hour; children aged 6 and above received 500 mg half an hour before the trip and, if necessary, 500 mg every 4 hour. Children randomized to receive dimenhydrinate took 12.5 to 25 mg half an hour before the trip and, if necessary, 25 mg every 4 hour. Physicians' rating of the therapeutic effectiveness

showed highly significant difference between the treatment groups ($P < 0.00001$). Results were good in 100% of treatment cases in the ginger group, while in the dimenhydrinate group, they were modest in 69.2% and good in only 30.8%. All subjects in the ginger group reported symptom reduction within 30 minutes of taking the extract, while 69.2% in the dimenhydrinate group reported a reduction in 60 minutes ($P < 0.00001$). No patient in the ginger group reported any side effects, while most (84.6%) of the dimenhydrinate patients suffered from side effects, including dryness of the mouth (69.23%) and vertigo (23.07%). The difference in the treatment group was highly significant ($P < 0.001$). It is unclear when reading the study whether all of the children traveled by the same mode(s) of transportation. Also, the randomization process did not appear to allow for well-matched groups with regard to severity of motion sickness.

While the studies all show a beneficial effect for ginger on motion sickness, all have methodological shortcomings.

Nausea and Vomiting of Pregnancy

Nausea is likely to affect more than 50% of pregnant women, and frequently disrupts family and work routines (18). The most extensively studied botanical for nausea and vomiting of pregnancy is dried ginger rhizome (*Z. officinale*). A systematic review of six double-blind, randomized controlled trials (RCT) assessing the safety and effectiveness of ginger in the treatment of pregnancy-induced nausea and vomiting concluded that ginger may be an effective treatment for nausea and vomiting in pregnancy (19). Four of the six RCT ($n = 246$) showed superiority of ginger over placebo; while the other two RCT ($n = 429$) indicated that ginger was as effective as the vitamin B6 in relieving the severity of nausea and vomiting episodes. Regarding safety, a prospective cohort observational study of 187 pregnant women and RCT (including follow-up periods) showed the absence of significant side effects or adverse effects on pregnancy outcomes. However, the authors noted that more observational studies, with a larger sample size, are needed to confirm the encouraging preliminary data on ginger safety.

Since the publication of the systematic review, three additional RCTs have been published. Two RCTs ($n = 196$) found that ginger (1000 mg/d and 650 mg t.i.d.) and vitamin B6 (40 mg/d and 25 mg t.i.d.) were both effective in reducing nausea and vomiting episodes (20,21). Chittumma et al. found that 650 mg t.i.d. of ginger was more effective than 25 mg t.i.d. vitamin B6 ($P < 0.05$), while the study by Ensiyeh et al. reported greater relief of nausea with ginger compared to vitamin B6. The other RCT compared 500 mg b.i.d. ginger powder to 50 mg b.i.d. dimenhydrinate over a period of 7 days (22). Dimenhydrinate was more effective for reducing vomiting episodes during the first 48 hours, though there was no difference from days 3 to 7. There was more drowsiness and sedation in the dimenhydrinate group.

In summary, clinical trials suggest that ginger may be considered a useful treatment option for women suffering from pregnancy-induced nausea and vomiting at doses ranging from 1000 to 1850 mg per day of powdered ginger.

Chemotherapy-induced Nausea and Vomiting

Chemotherapy-induced nausea and vomiting significantly reduces patients' quality of life, increases fatigue and anxiety, and increases costs of health care delivery. An abstract published in 1987 reported that of 41 patients with leukemia randomly assigned to receive either oral ginger or placebo after administration of intravenous compazine, there was a significant reduction in nausea in those who received ginger compared with those who received placebo (23). This report was followed by a small open study of 11 patients who were undergoing monthly photopheresis therapy (psoralen and the chemotherapy agent 8-MOP) and regularly complained of nausea as a result (24). Patients were given 1.6 g of powdered ginger 30 minutes prior to the administration of 8-MOP and then evaluated their nausea on a scale of 0 to 4. Total score for nausea decreased from 22.5 (individual average 2.045) prior to the trial to 8.0 (individual average 0.727) after administration of ginger. Three patients complained of heartburn. The study suffered from lack of blinding and placebo arm.

In 2003, a more rigorous randomized, prospective, crossover, double-blind study was carried out in 60 patients ($n = 50$) receiving cyclophosphamide in combination with other chemotherapeutic agents (10). Patients with at least two episodes of vomiting in the previous cycle were included and randomly assigned to receive one of three antiemetics: 1 g p.o. dried ginger powder given 20 minutes prior to chemotherapy and repeated 6 hours after chemotherapy; 20 mg IV metoclopramide 20 minutes prior to chemotherapy and 10 mg p. o. 6 hour after chemotherapy; or 4 mg IV ondansetron 20 minutes prior to chemotherapy and 4 mg p.o. 6 hours after chemotherapy. Lactulose capsules and normal saline IV were used, where appropriate, to maintain blinding. Patients were admitted to the hospital for 24 hours and observed for the incidence of nausea and vomiting, and adverse effects, if any, were recorded. Patients were crossed over to receive the other antiemetic treatments during the two successive cycles of chemotherapy. Complete control of nausea was achieved in 86% with ondansetron, 62% on ginger, and 58% with metoclopramide. Complete control of vomiting was achieved in 86% with ondansetron, 68% of patients on ginger, and 64% with metoclopramide. No adverse effects attributable to ginger were recorded. In summary, the antiemetic effect of ginger was comparable to that of metoclopramide, but ondansetron was found to be better than both.

A randomized, double-blind, placebo-controlled trial of 162 patients with chemotherapy-induced nausea and vomiting undergoing treatment at the University of Michigan failed to find any beneficial effect on nausea or vomiting when ginger was given after the start of chemotherapy with or without 5-HT₃ receptor antagonist and/or aprepitant. The study used two doses of ginger extract (1.0 g/d or 2.0 g/d) per day or a matching placebo. It should be noted that this was a 10:1 extract and each 250 mg capsule contained 15 mg (5%) total gingerols. A 10:1 extract typically means that 1-g extract is equivalent to 10 g crude herb equivalent. A relatively high dose compared to the doses of 1 to 2 g per day of powdered crude ginger used in other trials. This study did not pretreat with ginger but provided the first dose one hour after completing chemotherapy. Participants receiving the high dose

of ginger (2.0 g) reported having significantly more severe episodes of delayed nausea compared to both placebo and low-dose ginger (25).

A study of 644 patients undergoing chemotherapy randomly assigned them to receive either a placebo or one of three doses of ginger in capsule form (0.5 g, 1.0 g, or 1.5 g). The placebo or ginger was divided into two doses given each day for six days, starting three days before chemotherapy. Patients also received 5-HT₃ receptor antagonist plus dexamethasone (anti-nausea medications) on day 1 of chemotherapy. Information about nausea was collected during the first four days of the chemotherapy cycle. All three doses of ginger were more effective than the placebo at reducing nausea, though the two lower doses (0.5 g and 1.0 g) appeared to have the greatest effect and there was no effect on vomiting. These results suggest that the addition of ginger supplements to conventional antiemetic medications reduces chemotherapy-induced nausea (26).

Postoperative Nausea and Vomiting

Postoperative nausea and vomiting (PONV) is one of the most common complaints following anesthesia and surgery. The incidence of PONV is 20 to 30% during the first 24 hours after anesthesia. As a part of oral premedication, ginger is being studied due to its lack of known relevant side effects (e.g., sedation), high patient acceptance, and low cost (27). A meta-analysis of five randomized controlled trials ($n = 363$) found the relative risks of ginger for postoperative nausea and vomiting and postoperative vomiting were 0.69 (95%, confidence interval 0.54–0.89) and 0.61 (95%, confidence interval 0.45–0.84), respectively. Only one side effect—abdominal discomfort—was reported (28). Two additional placebo-controlled studies published after the meta-analysis were also positive for reduction of PONV when a minimum of 1 g ginger powder was given one hour prior to surgery (29,30).

Anti-inflammatory Activity

In vitro and animal models have shown that ginger inhibits both cyclo-oxygenase and lipo-oxygenase pathways (31). Intraperitoneal administration of crude hydroethanolic ginger reduced rat paw edema induced by carrageenan and inhibited serotonin-induced skin edema (32).

Osteoarthritis

Present-day therapy for osteoarthritis (OA) is principally directed at symptoms, since there is no well-established disease-modifying therapy. Treatments generally involve a combination of nonpharmacologic and pharmacologic measures, utilizing a combination of analgesia, and anti-inflammatory and intra-articular therapies (33). Srivastava and Mustafa (34) published two collections of anecdotal reports on the beneficial effects of ginger on rheumatological complaints more than a decade ago. Two clinical trials have been published since that time. Ginger extract (170 mg/day EV.EXT 33) was compared to placebo and ibuprofen (400 mg/day) in 67 patients ($n = 56$) with osteoarthritis of the hip or knee in a controlled, double-blind, double-dummy, crossover study with a wash-out period of one week followed by three treatment periods in a randomized sequence, each of three weeks'

duration. Acetaminophen was used as rescue medication throughout the study. The ranking of efficacy was ibuprofen > ginger extract > placebo for visual analog scale scores on pain and the Lequesne index, but no significant difference was seen when comparing ginger extract and placebo directly (35). The lack of positive effects may have been due to inadequate trial length and/or insufficient dose.

A randomized, double-blind, placebo-controlled study enrolled 261 ($n = 247$) patients with OA of the knee as diagnosed by the American College of Rheumatology classification criteria (36). The primary efficacy variable was the proportion of responders experiencing a reduction in "knee pain on standing," using an intent-to-treat analysis. A responder was defined by a reduction in pain of ≥ 15 mm on a visual analog scale. During the six-week treatment period, patients ingested one capsule twice daily of 255 mg ginger extract (EV.EXT 77, extracted from 2500 to 4000 mg of dried ginger rhizomes and 500 to 1500 mg of dried galanga rhizomes) or placebo. The percentage of responders experiencing a reduction in knee pain on standing was superior in the ginger extract group compared with the control group (63% vs. 50%; $P = 0.048$). Analysis of the secondary efficacy variables revealed a consistently greater response in the ginger extract group compared with the control group, when analyzing mean values: reduction in knee pain on standing (24.5 vs. 16.4 mm; $P = 0.005$) and reduction in knee pain after walking 50 ft (15.1 vs. 8.7 mm; $P = 0.016$). One group of adverse events showed a significant difference between treatment groups: GI adverse events were more common in the ginger extract group [116 events in 59 patients (45%)] compared with the placebo group [28 events in 21 patients (16%)]. None of the GI adverse events were considered serious by the investigators.

Both of these studies suggest the strong need for dose escalation studies that can determine the most efficacious dose that it is still safe and well tolerated. Studies of longer duration are also required before more definitive conclusions can be drawn about the safety, tolerance, and effectiveness of ginger for osteoarthritis.

Cardiovascular Effects

Ginger shows considerable anti-inflammatory, antioxidant, anti-platelet, hypotensive and hypolipidemic effect in in vitro and animal studies, all of which suggest that it may have a beneficial role in cardiovascular health (37). In vitro research has shown that constituents in ginger have an inhibitory effect upon cholesterol biosynthesis (38). Animal studies have demonstrated lipid-lowering activity via enhancement of the activity of hepatic cholesterol-7 α -hydroxylase, the rate-limiting enzyme in bile acid biosynthesis, thereby stimulating conversion of cholesterol to bile acids, an important mechanism for eliminating cholesterol from the body (39). A study in rabbits found that an orally administered ethanolic extract of ginger (200 mg/kg) reduced lipids after 10 weeks' feeding of a cholesterol-rich diet. The authors found that, at this dose, ginger produced results similar to those of gemfibrozil (40). In contrast to the in vitro and animal data, a study of patients with coronary artery disease found that three months ingestion

of 4 g/day dried ginger powder failed to lower blood lipids (41).

Ginger inhibits platelet aggregation in vitro, acting as a potent inhibitor of arachidonic acid, epinephrine, adenosine diphosphate, and collagen. A placebo-controlled study of eight healthy males found that ingestion of 2 g of ginger caused a dose-dependent reduction of thromboxane synthetase and prostaglandin synthetase; however, no differences were found in bleeding time, platelet count, or platelet function between the placebo and control groups (42). In patients with coronary artery disease (CAD), powdered ginger administered in a dose of 4 g/day for three months did not affect adenosine diphosphate- and epinephrine-induced platelet aggregation. However, a single dose of 10 g produced a significant reduction in platelet aggregation induced by the two agonists (41).

Gastrointestinal Effects

Ginger has long been valued in traditional medicine for a wide variety of GI complaints. Researchers are beginning to explore possible scientific explanations for these historical uses. In vitro research indicates that constituents present in ginger have antiulcer activity (43). Animal research demonstrates that ginger reduces the occurrence of gastric ulcers induced by nonsteroidal anti-inflammatory drugs (NSAIDs) and hypothermic-restraint stress (44). Chologogic activity has been documented in rats with the acetone extract of ginger (45).

Helicobacter pylori (HP) is the primary etiological agent associated with dyspepsia, peptic ulcer disease, and development of gastric cancer. Novel, inexpensive, and safe approaches to the eradication of HP are currently being sought. A methanol extract of the dried, powdered ginger rhizome, fractions of the extract, and the isolated constituents, 6-, 8-, and 10-gingerol and 6-shogaol, were tested against (19) strains of HP (46). The extract inhibited the growth of all (19) strains in vitro with a minimum inhibitory concentration range of 6.25 to 50 $\mu\text{g/mL}$. One fraction of the crude extract, containing the gingerols, was active and inhibited the growth of all HP strains with a minimum inhibitory concentration range of 0.78 to 12.5 $\mu\text{g/mL}$.

Ginger may be of benefit in patients with gastroparesis, which can present with signs and symptoms such as heartburn, gastroesophageal reflux, early satiety, abdominal bloating, and nausea and/or vomiting several hours after eating a meal. Twenty-four healthy volunteers were studied twice in a randomized double-blind manner (47). After an eight-hour fast, the volunteers ingested three ginger capsules (total 1200 mg) or placebo, followed after one hour by 500 mL of low-nutrient soup. Antral area, fundus area and diameter, and the frequency of antral contractions were measured using ultrasound at frequent intervals over 90 minutes, and the gastric half-emptying time was calculated from the change in antral area. Antral area decreased more rapidly ($P < 0.001$) and the gastric half-emptying time was less after ginger than placebo ingestion (13.1 ± 1.1 vs. 26.7 ± 3.1 min, $P < 0.01$), whereas the frequency of antral contractions was greater ($P < 0.005$). There was no significant difference in any GI symptoms.

DOSE

The dose for ginger varies considerably between products; especially with the growing numbers of highly concentrated ginger extracts being promoted for their anti-inflammatory effects. Reading and understanding the dose on product labels can be challenging for consumers and clinicians alike. For instance when the label states that each capsule contains "Ginger rhizome extract 250 mg," there is no way to know how much ginger is actually in the product as no strength is provided for the extract. If the product contains a 20:1 extract, each 250 mg capsule would actually provide 5000 mg of crude ginger. Imagine a pregnant woman being told to take 250 mg of ginger four times per day for nausea and vomiting of pregnancy, purchasing this type of product and actually getting 20,000 mg per day of ginger! This is a real problem in the marketplace. The following are a few doses (serving sizes) reported in the research and literature:

- Fresh or dried rhizome: 1 to 4 g daily (48). Note: dried is more effective for nausea and vomiting.
- Fluidextract: 1:1 (g/mL) 0.25 to 1.0 mL t.i.d.; tincture 1:5 (g/mL) 1.25 to 5.0 mL t.i.d. (48).

CONTRAINDICATIONS AND ADVERSE EFFECTS

Because of its cholagogic effect, some experts recommend that those with active gallstone disease avoid large doses of ginger. Patients treated with ginger have reported increased flatulence and heartburn compared to those on placebo.

HERB-DRUG INTERACTIONS

None are known. There have been anecdotal and speculative warnings about ginger and warfarin; however, there are no documented cases in the literature. Standardized ginger extract had no significant effects on coagulation parameters or on warfarin-induced changes in blood coagulation in rats (49). Though evidence is lacking for a direct interaction between warfarin and ginger (50), it is probably still wise for practitioners and patients alike to be cautious about the use of doses greater than 4 g/day of dried ginger in conjunction with antiplatelet/anticoagulant medications.

TOXICITY

There is little risk of toxicity when used as a spice. Acute toxicity tests in mice found no mortality or adverse effects when ginger extract was given at doses up to 2.5 g/kg (by lavage) over a seven-day period. Increasing the dose to 3.0 to 3.5 g/kg resulted in 10 to 30% mortality (51).

USE IN PREGNANCY

Two studies have been published examining the effect of ginger in pregnant rats. One found that ginger tea (20 or

50 g/L) administered from gestation days 6 to 15 and then sacrificed at day 20 significantly increased early embryonic loss and increased growth in surviving fetuses (52). No gross morphologic malformations were seen in the treated fetuses. Teratogenic studies on ginger extracts at doses of 100 to 1000 mg/kg failed to observe any toxic effects or early embryonic loss (53).

Researchers at the Hospital for Sick Children in Toronto, Canada, studied 187 pregnant women who used some form of ginger in the first trimester. They report that the risk of these mothers having a baby with a congenital malformation was no higher than that in a control group (7). Of the published human studies, there was 1 spontaneous abortion out of 32 in the ginger group (19), 1 spontaneous abortion of 27 in the crossover design study (20), and 3 spontaneous abortions of 60 in the ginger group (21), although one of these occurred in a woman who had not begun taking the treatment. Though the total number of women in these clinical trials is small, the rate of spontaneous abortion is not any greater than that seen in the general population.

CONCLUSIONS

The research to date for ginger is most compelling for its effects on the GI tract. There is little doubt that ginger has significant anti-emetic activity and research clearly shows that it can help ease the nausea and vomiting that occurs during pregnancy, or due to surgery or chemotherapy. The studies also suggest that lower doses of dried ginger (1–2 g) may be most efficacious for this purpose and that ginger must be given before and after chemotherapy for beneficial effects. As mentioned under the dosing section, researchers must be specific with regards to the type of extract used in the clinical trial as many readers will not understand that a 250 mg ginger extract (10:1) is equivalent to 2500 mg of crude ginger. And clinicians must be familiar with products in the marketplace in order to counsel patients about the safe and effective use of ginger for any medical condition.

The ability of ginger to enhance gastric motility and emptying in patients with heartburn and gastroparesis should be further explored. Many of our motility agents (e.g., metoclopramide) can have significant side effects, making natural remedies such as ginger an attractive alternative. In addition, ginger has gastroprotectant activity and is active against HP, an organism that is becoming more resistant to drug treatment and is a leading cause of gastric cancer around the world.

The potential role for ginger as an anti-inflammatory agent is intriguing based on basic science, though the limited human research has not been compelling. The studies also indicate that when patients consume high doses of 6 to 10 g of ginger each day, many will have gastric upset and irritation. Thus, better delivery systems and dosage forms will be necessary if this type of research is to continue. And if the National Institutes of Health is any indication of research interest, with more than eight clinical trials of ginger under way in 2010, there is probably much more we can learn from this popular and flavorful medicinal spice.

Ginkgo

Kristian Strømgaard, Stine B. Vogensen, Joseph Steet, and Koji Nakanishi

INTRODUCTION

The tree *Ginkgo biloba* L. has a long history of use in traditional Chinese medicine. The ginkgo tree is classified in its own family and order, and holds a special position in evolutionary plant history because it provides a connection between the seedless vascular plants and seed plants. In recent years, the leaf extract of *G. biloba* has become one of the most widely used herbal remedies and is sold as a phyto-medicine in Europe and as a dietary supplement worldwide. Ginkgo extracts are used for the treatment of cerebral dysfunction and circulatory disorders, and have been studied in several animal experiments and clinical trials. There are a wide variety of chemical constituents in the extract, with the principal components being ginkgolides and bilobalide (terpene trilactones, TTLs) and flavonoids.

BACKGROUND

Ginkgo biloba L., or the maidenhair tree (Fig. 1), is the only surviving member of its family (Ginkgoaceae) and order (Ginkgoales), underscoring its unique phylogenetic status. Fossil records show that the *Ginkgo* genus was present some 180 million years ago. The Ginkgoaceae peaked 130 million years ago, with numerous widespread species, but gradually gave way to modern angiosperms. Today, only one species, *G. biloba*, survives, and it occurs naturally only in eastern parts of China. The morphology of the ginkgo tree itself appears to have changed very little over 100 million years, and for this reason it is often called a “living fossil.”

The ginkgo tree takes its name from *ginkyo* in Japanese and *yinhsing* in Chinese; both words translate to “silver apricot,” referring to the appearance of the ginkgo nuts. The term “ginkgo” was first used by the German physician and botanist Engelbert Kaempfer in 1712, but Linnaeus provided the terminology “*Ginkgo biloba*” in 1771. The ginkgo tree can grow up to 40 m high, with a stem diameter between 1 and 4 m, and can reach an age of more than 1000 years. Vertical growth generally slows down with the onset of sexual maturity at around 25 years. The appearance of the tree varies from slim and conical to full and rounded, with gray bark deeply furrowed on old trees. The ginkgo tree has characteristic green, leathery, fan-shaped leaves that turn golden yellow in autumn. In young specimens, the leaves are divided into two distinct lobes, and hence the notation *biloba* (from Latin *bi*, double; *loba*, lobes). The Ginkgo species is dioecious, having separate male and female trees.

Among seed plants with a reproductive system, the ginkgo is a primitive tree, and its reproductive organs resemble those of seedless vascular plants such as ferns. Ginkgo provides an important evolutionary connection between seedless vascular plants and seed plants, as discovered by Japanese botanist Sakugoro Hirase more than a 100 years ago. In the spring, before the leaves emerge, male *G. biloba* trees produce catkins rich in pollen, while female trees produce 2- to 3-mm long ovules. Each ovule secretes a small mucilaginous droplet that catches the airborne pollen and transports it inside the ovule, where multiflagellated spermatozoids are produced. A spermatozoid fertilizes the female egg cell, and the seed is shed from the tree approximately one month after fertilization. Fully mature ginkgo seeds, also known as ginkgo nuts, have a pungent smell due to the presence of butanoic and hexanoic acids in the fleshy sarcotesta surrounding the seed (Fig. 2) (1).

Figure 1 A *Ginkgo biloba* tree.

Figure 2 Leaves and nuts of *G. biloba*.

Cultivation and History of Use

The ginkgo tree has been cultivated in China for several thousand years and, according to some of the earliest written ginkgo tree references dating back to the Song dynasty of the early 11th century, the tree was appreciated for its beauty and for its edible nuts. The tree was introduced into Japan from China in the 12th century, and some 500 years later into Europe and North America. The use of *G. biloba* for medicinal purposes was first mentioned in 1505 A.D. in a book by Liu Wan-Tai. In the Chinese materia medica *Pen Tsao Ching* from 1578, *G. biloba* is described as a treatment for senility in aging members of the royal court. In these old records, it is mainly the use of nuts that is described. Raw ginkgo nuts without the fleshy sarcotesta are described in traditional Chinese medicine as a treatment for a variety of lung-related ailments, including asthma and bronchitis, as well as some kidney and bladder disorders. The use of *G. biloba* leaves has played only a minor role in traditional Chinese medicine, but in the modern Chinese Pharmacopoeia, the leaves are considered beneficial for the heart and lungs.

The ginkgo tree can persist in conditions of low light and nutrient scarcity and is highly resistant to bacteria, fungi, and viruses. Furthermore, it is resistant to air pollution; this has made *G. biloba* a popular roadside tree in urban areas of Japan, Europe, and northern America. In China, the ginkgo tree is cultivated partly to meet demands for ginkgo nuts, a delicacy in Chinese and Japanese cuisine alike. The kernel is obtained by boiling the nuts until the hard shell cracks open; this kernel is subsequently boiled with sugar or roasted. Unfortunately, raw ginkgo nuts contain the toxin 4-O-methylpyridoxine, which can result in serious food poisoning.

Ginkgo biloba Extract

For pharmaceutical purposes, an extract of *G. biloba* leaves was first introduced in Western countries in 1965 by the German company Dr. Willmar Schwabe under the trade name Tebonin. Later, Schwabe established a collaboration with the French company Beaufour-Ipsen, and to-

gether they developed a standardized *G. biloba* extract (GBE) termed EGb 761 (Extrait de *Ginkgo biloba* 761), which was sold under trade names such as Tanakan, Rökan, and Tebonin forte. Other *G. biloba* products have entered the market, and GBE is now among the best selling botanical preparations worldwide. Rising demand for GBE has spurred the increased harvesting of *G. biloba* leaves, and today, more than 50 million *G. biloba* trees are grown, especially in China, France, and the United States, producing approximately 8000 tons of dried leaves each year. The yellow or green leaves are harvested in mid-to-late summer and then dried and pulverized. Through various extraction procedures, the active constituents are concentrated and undesired constituents such as organic acids are discarded. The composition of the leaf extract varies considerably and is related to the age of the plant, growth conditions, and time of harvest. To ensure the quality of GBE and the concentration of flavonoids and terpene trilactones, the presumed active constituents have been standardized.

CHEMISTRY AND PREPARATION OF PRODUCT

Ginkgo leaves contain a wide variety of phytochemicals, including alkanes, lipids, sterols, benzenoids, carotenoids, phenylpropanoids, carbohydrates, flavonoids, and terpenoids, particularly terpene trilactones (2). The major constituents are flavonoids and polyphenolic compounds that are widely distributed in the plant kingdom and are found in all green plants. Flavonoids are pigments responsible for the colors yellow, orange, and red in autumn leaves and various flowers, and are also present in wine and tea. To date, more than 30 flavonoids have been found in *G. biloba*; the diversity arises from different glycoside substitutions of the flavonol aglycone. The flavonoids of GBE are almost exclusively flavonol-O-acylglycosides, including mono-, di-, or triglycosides of the flavonol aglycones quercetin and kaempferol primarily substituted at the 3-position (Fig. 3). Additionally, nonglycosidic biflavonoids, such as bilobetin, ginkgetin, and isoginkgetin (Fig. 3) and proanthocyanidins such as procyanidin and prodelphinidin have also been isolated from *G. biloba*.

The TTLs comprise five diterpenes named ginkgolide A, B, C, J, and M and the sesquiterpene bilobalide. These compounds are unique and found only in the ginkgo tree. The ginkgolide cage structure consists of six 5-membered rings, including three lactones, a tetrahydrofuran ring, and a spiro[4.4]nonane skeleton. The ginkgolides differ in the positions and numbers of hydroxyl groups on the spirononane framework. In bilobalide, rings A and F are absent and the tetrahydrofuran ring of the ginkgolides (ring D) is replaced by a lactone. The ratios of TTLs vary by season and between different parts of the tree.

The TTLs are unique constituents of the ginkgo tree and have attracted great interest because of their complex structures and reported biological activities (3). Ginkgolides were first isolated from the root bark of *G. biloba* by S. Furukawa in 1932, and their structures were elucidated in 1967. The structure of bilobalide was determined in 1972. The ginkgolides have inspired many studies, particularly as targets for complex total synthesis, as

Figure 3 Structures of flavonoids.

templates for structure–activity relationship studies, and as terpenes with a surprising and novel biosynthetic pathway. Prior to these studies, it was thought that all terpenes were biosynthesized through the mevalonate pathway, but by examining the biosynthesis of ginkgolides, Arigoni and coworkers proved that terpenes can be synthesized through the deoxyxylulose phosphate or nonmevalonate pathway (4).

Formulation and Analysis

Standardized extracts (dry extracts from dried leaves, extracted with acetone and water) contain 22% to 27% flavone glycosides and 5% to 7% terpene lactones, of which approximately 2.8% to 3.4% are ginkgolides A, B, and C and 2.6% to 3.2% is bilobalide. Qualitative and quantitative determination of flavonoid glycosides is carried out after hydrolysis to the aglycones kaempferol, quercetin, and isorhamnetin. The qualitative presence or absence of biflavones is determined by high performance liquid chromatography. Qualitative and quantitative determination of TTLs (ginkgolides and bilobalide) is by high performance liquid chromatography or gas–liquid chromatography. Certain commercial products such as EGb 761 do not contain biflavones, and the level of ginkgolic acids should be below 5 mg/kg, because of their allergenic potential. Coated tablets and solutions for oral administration are prepared from these standardized, purified extracts.

PRECLINICAL STUDIES

A vast number of preclinical studies have investigated the *in vitro* and *in vivo* effects of GBE as well as the individual components of GBE, particularly the TTLs, ginkgolides and bilobalide. The major components of all GBEs are flavonoids and TTLs, and it is believed that these two classes of compounds are responsible for the biological effects of GBE. In most cases, GBE has been investigated in *in vitro* or *in vivo* assays, or the extracts have been

screened in DNA arrays. The other primary approach has been to investigate single chemical components, such as the flavonoids, ginkgolides, and bilobalide, in a wide variety of assays. Although many biological effects can be explained by the individual components, it has often been suggested that GBE acts by a synergistic mechanism. The effects of GBE can be grouped into three related categories: (i) effects related to antioxidant activity; (ii) effects on gene expression; and (iii) direct effect on protein function, with these effects sometimes overlapping or being related.

The antioxidant effects of GBE are well documented, particularly using *in vitro* studies. These effects are most likely because of the flavonoids, which are well-known free radical scavengers and antioxidants. Specifically, it has been shown that GBE can scavenge nitric oxide, protect against lipid peroxidation of low-density lipoproteins, and inhibit the formation of oxygen radicals. It is believed that numerous disease states are related to free radicals. Therefore, it has been speculated that the antioxidant effects of GBE could be used to treat diseases such as atherosclerosis and cancer, as well as a number of neurodegenerative diseases such as Alzheimer's and Parkinson's disease.

The effects of GBE on gene expression have been the subject of several investigations in recent years, and a general consensus has emerged that this effect is critically important when looking at the clinical effects of GBE (5). Gohil and coworkers used high-density oligonucleotide microarrays to study neuromodulatory effects in mice that had EGb 761-supplemented diets (6). Twelve thousand genes and expressed gene tags from the hippocampus and cerebral cortex of the mice were analyzed for changes in gene expression, and of these, 10 were found to change more than threefold as a result of EGb 761 administration. Several of these 10 genes may be relevant to neurodegenerative disorders.

In another approach, the expression of peripheral benzodiazepine (PB) receptors, proteins involved in cholesterol transport and many other biological events, was studied (7). Animal studies have shown that GBE treatment decreases cell proliferation in tumors with PB

receptor overexpression (8). Most clinical studies of GBE have looked at effects on various forms of neurodegenerative disease, particularly as potential treatment of Alzheimer's disease (AD). Together with the accumulation of intracellular neurofibrillary tangles, deposition of β -amyloid plaques is the primary indication for AD, and it is believed that an increase of β -amyloid plaques is central to the pathogenesis of AD. Therefore, the recent findings that GBE and individual ginkgolides (9) can inhibit β -amyloid aggregation (10), as well as prevent neuropathy and neuron dysfunction (11), form the basis for continued research into the effects of GBE in relation to AD. The two major components of GBE are flavonoids and TTLs, and in contrast to the wealth of studies that have been performed using GBEs, far fewer investigations have looked at the effect of the individual components of these extracts. However, flavonoids and TTLs are thought to be responsible for most of the pharmacological properties of GBEs. An important consideration when looking at the effects on the central nervous system (CNS) is the bioavailability, including penetration of the blood-brain barrier, of these components. It has been assumed that the bioavailability of flavonoids is low, whereas TTLs, in particular the ginkgolides, are nearly completely bioavailable. Recent studies indicate that ginkgolides can penetrate the blood-brain barrier, although only in limited amounts. Though such studies cannot predict which of the components of GBE are efficacious, bioavailability is obviously a critical parameter when evaluating the physiological effects of GBE.

Flavonoids possess many biological activities, and they act as antioxidants, free radical scavengers, enzyme inhibitors, and cation chelators. They also show anti-inflammatory, antiallergic, anti-ischemic, immunomodulatory, and antitumoral action (12). The pharmacological effects of flavonoids in GBE have mainly been attributed to their utility as antioxidants and free radical scavengers. Because the flavonoids present in GBE are almost entirely flavonol glycosides, it is expected that these compounds or their metabolites play a key role in these events; however, as mentioned above, their bioavailability might be a limiting factor.

The number of studies on the biological effects of ginkgolides increased dramatically in 1985, when it was reported that ginkgolides, particularly ginkgolide B (GB), are antagonists of the platelet-activating factor (PAF) receptor. The clinical application of GB (BN 52021) as a PAF receptor antagonist was investigated, but, as is true of all other antagonists of the PAF receptor, GB was never registered as a drug, primarily because of a failure to demonstrate efficacy. The clinical studies, however, showed that GB was well tolerated and showed very few, if any, side effects. A large number of ginkgolide derivatives that have been prepared and tested for their ability to antagonize the PAF receptor and several derivatives showed increased potency in comparison to the native ginkgolides. Together, these studies have led to a clearer understanding of the structural features required for PAF receptor antagonism (3).

Recently, it was found that ginkgolides are potent and selective antagonists of glycine (Gly) receptors. The Gly receptors are found primarily in the spinal cord and

brain stem, as well as in higher brain regions such as the hippocampus. They are, together with γ -aminobutyric acid (GABA_A) receptors, the main inhibitory receptors in the CNS. Electrophysiological studies showed that GB antagonizes Gly receptors in neocortical slices (13) and hippocampal cells (14), and suggested that GB binds to the central pore of the ion channel, acting as a noncompetitive antagonist. Molecular modeling studies showed a striking structural similarity between picrotoxinin, an antagonist of both GABA_A and Gly receptors, and ginkgolides (13). Thus, ginkgolides are highly useful pharmacological tools for studying the function and properties of Gly receptors. However, the physiological importance of this antagonism remains to be investigated.

Several studies have shown that ginkgolides, particularly ginkgolide A and ginkgolide B can modulate PB receptors. These receptors are located mainly in peripheral tissues and glial cells in the brain, and are distinct from the benzodiazepine site on GABA_A receptors. PB receptors are typically located on the outer membranes of mitochondria. The function of PB receptors is not entirely clear, but involvement in steroidogenesis, cell proliferation, and stress and anxiety disorders has been suggested. The primary action of GB is the inhibition of the expression of PB receptors (15). Several studies have indicated that ginkgolides also protect against various damaging CNS events, such as excitotoxicity, ischemia and other cerebrovascular and traumatic brain injury, as well as inflammation. The mechanisms behind these effects are not entirely clear and are probably multifaceted.

Bilobalide (BB) is the predominant TTL found in GBE. A wealth of pharmacological evidence indicates that BB might be a very important compound when looking at neuromodulatory properties of *G. biloba* constituents. Several studies have shown that BB affects the neuronal transmission mediated by the neurotransmitters glutamate, GABA and glycine, but the mechanism of action is still unclear. BB has been found to interfere with the release of glutamate under hypoxia/hypoglycemic conditions. Furthermore, it was demonstrated that BB is an antagonist of GABA_A receptors (16), but this effect seems only to account for a small part of the neuroprotective effect of BB (17).

Because antagonists of inhibitory receptors, particularly GABA_A and glycine receptors, are known convulsants, the result of BB acting on GABA_A receptors and ginkgolides on glycine receptors could pose a risk to patients ingesting GBE. In confirmation, a study of two epileptic patients showed an increased frequency of seizures with GBE administration. This increase was reversed when the patients stopped taking the extract (18). These results indicate that people with a low seizure threshold, such as epileptic patients, should be cautious when taking GBE.

Potential medicinal applications of BB have been described in patents, including use of BB for the protection of neurons from ischemia, as an anticonvulsant, and for treatment of tension and anxiety. BB inhibits brain phospholipase A₂ activity, leading to a neuroprotective effect, and several studies have shown that BB preserves mitochondrial respiration, especially under ischemic conditions.

CLINICAL STUDIES

A large number of clinical trials have been conducted using GBEs and, in most cases, these trials have examined effects related to dementia. Specifically, changes in memory, thinking, and personality in aging people were studied. In almost all of these investigations, the standardized extract EGb 761 was administered and, although various dosing regimens were employed, daily doses of 120 to 240 mg EGb 761 were most commonly used.

Generally, clinical studies have shown that GBE can lead to an improvement in the symptoms associated with cerebral insufficiency, such as memory loss, depression, and tinnitus. In Germany, GBE is registered as an herbal medicine to treat cerebral insufficiency. This is a diagnosis covering a range of conditions, as illustrated by the list of indications from the German Commission E: "disturbed performance in organic brain syndrome within the regimen of a therapeutic concept in cases of demential syndromes with the following principal symptoms: memory deficits, disturbances in concentration, depressive emotional condition, dizziness, tinnitus, and headache. The primary target groups are dementia syndromes, including primary degenerative dementia, vascular dementia, and mixed forms of both (19)." In two seminal clinical studies, a total of 549 AD patients were evaluated for effects of EGb 761 treatment (20,21). In both studies, EGb 761 significantly slowed the loss of cognitive function, which is a symptom of dementia, and regression on certain data points was delayed by 7.8 months, which is comparable to the currently available AD treatments—Aricept (donepezil, 9.5 mo) and Exelon (rivastigmine, 5.5 mo), both acetylcholinesterase inhibitors.

Kleijnen and Knipschild reviewed 40 GBE clinical studies, which examined the efficacy of GBE in cerebral insufficiency (22). In the studies, the standard dose was 120 mg/day for at least four to six weeks. Of the 40 trials, only 8 were considered to be of acceptable methodological quality. The problems with many of the studies included small patient numbers, inadequate description of randomization procedures, inadequate patient characterization, and insufficient data presentation. Essentially, all the eight acceptable trials reported positive results, and no serious side effects were reported. It was concluded that future studies could provide a detailed efficacy assessment of GBE treatment. A more recent review by Knipschild and colleagues summarized 55 additional clinical studies, which also looked at the effect of GBE on cerebral insufficiency. Knipschild reports that although there is good evidence for a GBE effect, this evidence was obtained from an excessively small patient population and further, larger trials are required (23).

A meta-analysis systematically reviewed more than 50 clinical studies on GBE for the treatment of dementia and cognitive malfunctions associated with AD. Only 4 of the 50 studies met the inclusion criteria for the evaluation; these 4 studies included more than 400 patients. It was concluded that administration of 120 to 240 mg of GBE for three to six months had a small but significant effect on objective measures of cognitive function in AD, without significant adverse effects in formal clinical trials (24).

In 2002 and 2003, two clinical studies cast doubt on the positive clinical effect of GBE seen in almost all previous investigations. Both these studies included a larger number of patients, were carefully designed, and were randomized, double-blinded, and placebo-controlled. Knipschild et al. completed a clinical trial with 214 patients, who received GBE for 24 weeks. The patients suffered from either dementia or age-associated memory impairment, and no GBE treatment-related improvement was seen (25). In another study with 203 people older than 60 years who were given GBE for six weeks, no beneficial effect from the GBE treatment was observed (26); the results of this investigation have been heavily debated. In an evaluation from the Cochrane Library, Birks and Evans have critically reviewed 33 clinical studies, which were all randomized and double blind (27). The duration of the studies varied from 3 to 52 weeks, although the majority were conducted for 12 weeks. The participants were all diagnosed with either dementia or age-associated memory impairment, although some of the earlier studies did not fully verify the diagnoses. In their conclusion, Birks and Evans state that GBE appears to be safe and with no side effects compared to placebo, and that there is promising evidence for improved cognition and function with GBE treatment. However, the authors also note the results of recent trials that did not show GBE-related improvement, and therefore suggest that further clinical trials are required.

From 2000 to 2008 the U.S. National Institutes of Health sponsored the Ginkgo Evaluation of Memory Study, which enrolled 3069 volunteers aged 75 and older across five academic medical centers. This randomized, double-blind, placebo-controlled clinical trial found no effects of GBE in the rate of AD and all-cause dementia (28). Because the study is regarded as sufficient in scale and observational duration, but contradicts convincing preclinical evidence, the focus of research is shifting to whether the current standard GBE schedule is sufficient in terms of both daily amount and dosing duration (29). In France, the pharmaceutical company Ipsen is sponsoring another clinical trial, the GuidAge study, which aims to examine prevention of AD in patients older than 70 years with memory impairment. The results of this 2854-patient study are expected in 2010 (30) and will be of major importance in the continued evaluation and determination of the effects of GBE in relation to dementia.

A primary function of GBE may be to improve blood flow and to inhibit platelet aggregation, the latter through inhibition of the PAF receptor by ginkgolides. Therefore, the vascular effects of GBE administration naturally invite examination, and a number of clinical trials have looked at effects of GBE treatment in relation to peripheral vascular conditions. A meta-analysis of clinical trials investigating the effect of GBE on intermittent claudication, an early symptom of peripheral arterial disease, was carried out by Pittler and Ernst (31). Of 12 clinical trials conducted, 8 were included in this analysis, and the authors concluded that GBE is superior to placebo in the symptomatic treatment of intermittent claudication. However, it was noted that the overall magnitude of the treatment effect was modest and its clinical relevance was uncertain.

The effect of GBE on healthy people has also been examined. Several clinical studies indicate improved cognitive functions. This effect is still controversial, as illustrated by a recent evaluation of the clinical trials studying GBE efficacy in healthy persons (32). Canter and Ernst found nine placebo-controlled double-blind trials, which were generally of acceptable methodological quality. None of these short-term (< 31 days) trials indicated consistent positive effects from GBE treatment. The authors conclude that the benefit from GBE on cognitive function is not proven and that there is a particular need for further long-term investigations with healthy subjects (32).

Several studies have looked at the adverse effects and toxicity of GBE. Generally very few, if any, serious side effects from GBE have been found. Studies of acute GBE toxicity in mice and rats showed that doses of up to 10 g/kg did not result in lethal effects and higher doses could not be administered. In chronic toxicity studies with rats, doses up to 500 mg/kg caused no significant changes that could be observed after sacrificing the animals. In vitro studies and studies in mice and rats showed no mutagenic, carcinogenic, or teratogenic effects. In humans, the toxicity of orally administered GBE is generally considered low, and no significant interactions with other medications have been reported. Hemorrhage has been reported in connection with the use of Ginkgo products but a clear causality between intake of GBE and bleeding could not be established.

CONCLUSION

In conclusion, there is mounting evidence from clinical studies to suggest that GBE may positively affect a range of cognitive and peripheral vascular conditions. Other recent studies have questioned the benefit of GBE on cognitive disorders, but ongoing clinical trials seek to settle this controversy in the future. There is no evidence for any adverse effects from GBE administration.

REGULATORY STATUS

In most European countries, GBE is registered as an herbal medicine, whereas it is available as a dietary supplement in the United States.

ACKNOWLEDGMENTS

We are grateful to Prof. Per Mølgaard (Copenhagen, Denmark), Prof. Sergei Dzyuba (Texas Christian University, TX, U.S.A.), and Ms. Sonja Krane (New York, U.S.A.) for comments on the manuscript.

Ginseng, American

Chong-Zhi Wang and Chun-Su Yuan

INTRODUCTION

Ginseng has been widely used for thousands of years as a traditional medicine in many oriental countries. During the past few decades, ginseng roots and their extracts have also become increasingly popular in the United States and Europe as dietary supplements and additives to foods and beverages. American ginseng (*Panax quinquefolius*) and Asian ginseng (*Panax ginseng*) are the two most recognized herbs around the world. Based on Traditional Chinese Medicine theory, Asian ginseng is considered to stimulate and invigorate yang, whereas American ginseng is considered to calm and nourish yin while promoting the secretion of bodily fluids (1,2).

American ginseng has gained impressive popularity with the American public in the past 20 to 30 years. It is now cultivated with a production of over 1000 tons of dried roots in the northern United States, Canada, and northeastern China. The biologically active constituents of this plant have been pursued extensively and it is accepted that the triterpene saponins called ginsenosides are the major active ingredients (3,4). Ginsenosides are also distributed in many plant parts of the herb, including the roots, leaves, flowers, and berries. American ginseng is reported to have a wide range of therapeutic and pharmacological applications, such as tonic, anti-aging, immunomodulating, anti-fatigue, antidepressant, anti-diabetic, and anti-tumor activities (5,6).

The medical importance of American ginseng has led to the development of a wide spectrum of analytical methods for the determination of the total saponin content, target compound analysis, and group-specific analysis or metabolite profiling. The pharmacokinetics and metabolism of different compounds from American ginseng have been studied and discussed in animals and human subjects (7).

American ginseng is generally considered safe when used orally. The Food and Drug Administration (FDA) has previously considered ginseng as "generally recognized as safe" or "GRAS." However, adverse effects after ginseng administration have been reported, and ginseng may also interfere with prescription drugs, and interact with food, and diseases or conditions. During the last 10 years, more than 1000 publications on American ginseng focused on biological activities, clinical investigations, chemistry and analysis, as well as pharmacokinetics and potential ginseng-drug interactions have been reported and highlighted.

BACKGROUND

As a member of the plant family Araliaceae, American ginseng (*Panax quinquefolius* L.) is distributed in the eastern temperate forest areas of North America from southern Quebec to Minnesota in the north to Oklahoma, the Ozark Plateau, and Georgia in the south. The part of the plant commonly used in remedies is the root. It was first introduced in the "New Compilation of Materia Medica" by Yi-Luo Wu in 1757 (8). In the western world, it was recorded in Quebec, Canada, by Father Lafitau in the early 18th century, and since then has generated a lot of interest (9). This perennial herb thrives in hardwood forests on the north- and east-facing slopes in predominantly porous, humus-rich soils that receive a lot of rain. American ginseng also grows on southwest-facing slopes, in soils where sand or clay is characteristic, and in forests with conifers and softwoods, but most wild populations thrive in upland, north- and east-facing woods where shade and loam soils are typical. Methods of cultivation, botanical characteristics, and authentication of this medicinal plant have been extensively described (10). There are three kinds of American ginsengs available on the market: cultivated (organic and inorganic), simulated wild, and wild. Like all ginsengs, those growing wild are the best, and the most expensive.

CHEMISTRY AND PREPARATION OF PRODUCTS

Chemistry

Up to 2009, approximately 150 constituents including saponins, polysaccharides, polyacetylenes, phytosterols, oils, acids, carbohydrates, flavonoids, nitrogen-containing compounds, and vitamins have been isolated and characterized from American ginseng (11). The major and most important bioactive components are triterpene saponins. Most of the saponins are dammarane glycosides (12).

More than 60 saponins have been isolated from different parts of this plant including roots, leaves, stems, flower buds, and berries. These different saponins, however, can be divided into two major groups; some such as ginsenosides Rb₁, mRb₁, Rb₂, mRb₂, Rb₃, Rc, mRc, Rd, mRd, Rg₃, 20(R)-Rg₃, Rh₂, and quinquenosides I, II, III, V, and R₁ belong to the protopanaxadiol group. Others like ginsenosides Re, Rg₁, Rg₂, 20R-Rg₂, Rg₈, Rh₁, and 20R-Rh₁ belong to the protopanaxatriol group (13–15). In addition, other saponins such as ginsenoside Ro (oleanane

type), pseudoginsenoside F₁₁ (ocotillol type) have also been isolated from American ginseng (5). During the past two years, new ginsenosides have been continuously isolated and elucidated, these include quinquenoside L₁₇ (16), quinquefoloside-Lc (17), quinquenosides L₁₀, L₁₄, and L₁₆ (18,19), and new acetylated ginsenosides (19). Zhu et al. (20) isolated a new ceramide from transgenic crown galls of American ginseng. While conducting a research on the flower buds, Nakamura et al. (21) isolated five new dammarane-type triterpene glycosides, floralquinquenosides A, B, C, D, and E, together with 18 known dammarane-type triterpene glycosides and 3 flavonoid glycosides.

Polysaccharides and glycoproteins are also important bioactive compositions in American ginseng. In bioassay-guided isolation, a water-soluble polysaccharide PPQ5-2, which shows lymphocyte stimulation and interleukin-induction activities, was isolated and characterized (22). Another polysaccharide, Cvt-e002, was isolated and observed to reduce the allergic immune response in vitro (23). Dried American ginseng root contains 24.9% to 28.9% of starch and 11.0% to 12.4% of proteins (11).

Preparation and Analysis

Different solvents and methods were utilized to prepare extracts from American ginseng roots. Refluxing in 100% methanol was found to have better extraction efficiency than water or 70% aqueous methanol extraction (24). Ligor et al. (25) compared accelerated solvent extraction, the ultrasound-assisted solvent extraction, and mechanical shaking-assisted solvent extraction, finding the highest extraction efficiency during shaking. Using supercritical fluid extraction, Wood et al. (26) observed that up to 90% of the total ginsenosides were extracted compared to conventional methanol Soxhlet. This led to the isolation and characterization of a novel 6''/6'''-mono-*O*-acetyl ginsenoside Rb₁.

For analysis of constituents in American ginseng, conventional spectroscopies such as Fourier transform infrared spectroscopy and Raman spectroscopy were seldom applied (27,28). High-performance liquid chromatography (HPLC) was the most often used technique for ginsenoside analysis because it is low-cost, readily available, and easy to use. The ultraviolet (UV)/diode array detector (DAD) or evaporative light scattering detector (ELSD) were the routinely used detectors. For the UV detector, the detection wavelength was normally set at 202 nm owing to very few chromophore groups of ginsenosides. The UV detection showed a good linearity in a 100 time ranges of concentration, and a limit of 10 ng of ginsenosides on the column (29). In contrast, the sensitivity of the ELSD was found to be five times lower than that obtained with the UV, with minimum detectable concentration of 50 ng of ginsenosides on the column (30). In view of the better sensitivity and easier handling, the UV is recommended for the routine analysis of American ginseng samples. Recently, HPLC coupled with mass spectrometry (MS) has become the widely used technique for both qualitative and quantitative analysis of ingredients in American ginseng. HPLC-MS combines the efficient separation capability of HPLC and great

power of structural characterization and high sensitivity and selectivity of MS detection. The glycosidic linkages, the core, and the attached sugar(s) of the ginsenosides can be determined (31). Using high performance liquid chromatography-atmospheric pressure chemical ionization-mass spectrometry (HPLC-APCI-MS), a total of 30 ginsenosides were identified and characterized, the differences of ginsenoside profile can be used to distinguish Asian and American ginseng (32,33).

Based on component analysis and comparison, individual and total ginsenoside contents vary substantially among *Panax* species and ages, among different origins, and among different plant parts. In general, the content in wild grown root is higher than that in cultivated ones. However, there is a high variation of dry weight and total ginsenoside contents of individual wild roots ranging from 1% to 15% (34), which is likely influenced by genotype and environmental factors. Ginsenosides Rb₁, Rb₃, Rc, Rd, Re, and Rg₁ are six major saponins in American ginseng, accounting for more than 70% of total ginsenoside contents (2). Overall, ginsenoside Rb₁ is the most abundant, followed by Re and Rg₁/Rd. It is interesting to note that concentrations of Rg₁ and Re are inversely related among and within populations (35). Among different plant parts of American ginseng, the leaves, berries, rootlets, and rhizomes contain higher ginsenoside contents, followed by the main roots and stems. The leaves contain dramatically high levels of ginsenoside Rb₃ and Rd, the berries have the highest concentration of ginsenoside Rb₃, up to 5.35% (36), while higher contents of Rb₁ and Re are present in the main roots, rootlet, and rhizomes. The total contents of ginsenosides in main roots, rootlet, and rhizomes increase with the age of the plant. In contrast, the ginsenoside contents in the leaves and stems decrease with a year of growth (37).

The chemical composition and content of the steamed American ginseng is quite different from the fresh one. During the steaming process for American ginseng roots, ginsenosides Rg₁, Re, Rb₁, Rc, Rb₂, Rb₃, and Rd decreased while ginsenosides Rh₁, Rg₂, 20R-Rg₂, Rg₃, and Rh₂ increased. Ginsenoside Rg₃, a recognized anti-cancer compound, increased significantly between 0.5 to 3 hours of steaming. Heat processing increased the antiproliferative effect of American ginseng significantly (38). A similar phenomenon is observed for American ginseng berries (36).

PRECLINICAL STUDIES

Effects on Cardiovascular System

Cardiovascular disease continues to be the leading cause of death in the United States. Recent studies have incriminated reactive oxygen species in the pathogenesis of both acute and chronic heart disease. Many botanicals possess anti-oxidant properties, and these herbal anti-oxidants may protect against cardiovascular diseases by contributing to the total anti-oxidant defense system of the human body. Earlier studies have suggested that extract from the stems and leaves of American ginseng improves the lipid profile of hyperlipidemic rats and has anti-oxidant properties in cultured rat cardiac myocytes (39). Total American ginseng saponins administered to rats having the

myocardium damaged by injury to the left anterior descending coronary artery were also shown to protect the myocardium with an anti-ischemic action probably related to a decrease in free fatty acid levels and an elevation of lactate dehydrogenase activity. The total saponins may also have produced a Ca^{2+} channel blocking effect (40). American ginseng root saponins also displayed the ability to significantly decrease platelet aggregation rates and to increase superoxide dismutase activity in hyperlipidemic rats (41).

The acute anti-oxidant and protective effect of American ginseng berry extract (AGBE) has been demonstrated in cultured cardiomyocytes (42). Later works suggest that pretreatment with AGBE upregulates peroxide detoxifying mechanisms, which could affect intracellular oxidant dynamics in cardiomyocytes (42,43). A detailed study has shown that ginsenoside Re, the major constituent in AGBE, functions as an anti-oxidant, protecting cardiomyocytes from oxidant injury induced by both exogenous and endogenous oxidants, and that its protective effects may be mostly attributed to scavenging H_2O_2 and hydroxyl radicals (44). In an acute myocardial infarction (AMI) rat model, the effect of American ginseng saponin can protect myocardium from ischemic injury in rats after AMI by way of promoting angiogenesis in the infarcted or ischemic area of myocardium and upregulating expressions of vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) in myocardial cells (45). The anti-oxidant components and properties of American ginseng and their potential role in treating cardiovascular illness have been reviewed, the anti-oxidant activities of active constituents, and the relationship between their chemical structures and biological functions was also discussed (46,47).

Antihyperglycemic Effects

Type II diabetes is a serious chronic metabolic disorder worldwide. This disease represents a syndrome with disordered metabolism of carbohydrate and fat. The hypoglycemic ability of ginseng root extracts has been known for a few decades (48). Based on previous reports, extracts from American ginseng root, leaf, and berry showed antihyperglycemic activities.

Early research showed that both American ginseng and Asian ginseng roots possess significant anti-diabetic effects in C57 BL/6J ob/ob and C57 BL/Ks db/db mice (49–51). Ginsenoside Rb₁, the major constituent in American ginseng root, was found to possess anti-diabetic and insulin-sensitizing activities (52). It was reported that ginsenoside Rb₁ stimulates glucose transport in insulin-sensitive cells by promoting translocations of glucose transporter 1 (GLUT1) and glucose transporter 4 (GLUT4) by partially activating the insulin signaling pathway (53). In a separate study, ginsenoside Rb₁ was observed to promote glucose-stimulated insulin secretion through protein kinase A (PKA), which augmented insulin receptor substrate 2 (IRS2) expression to enhance insulin/insulin-like growth factor 1 (IGF-1) signaling (54). In addition to ginsenosides, other compounds from American ginseng root also showed anti-diabetic effects. An activity-guided fractionation and isolation of the American ginseng root extract led to identification of three glycans, quinquefolans

A, B, and C, which displayed hypoglycemic effects in normal and alloxan-induced hyperglycemic mice (55).

It is believed that nutrients did not accumulate beyond the root of the American ginseng plant, and thus research into its parts shied away from testing the leaf and berry for medicinal effects. Not surprisingly, there was no previous information on the biological activity of American ginseng leaf and berry. Our work demonstrated significant antihyperglycemic activity with the American ginseng leaf and berry extracts. Following a 12-day treatment using ob/ob mouse model, which exhibits profound obesity and hyperglycemia, to test the pharmacological effects of the extracts, we observed that both 150 and 50 mg/kg groups of the American ginseng leaf extract significantly decreased fasting blood glucose and improved glucose disposal in ob/ob mice suggesting an improvement in insulin sensitivity (56). Pharmacological studies on the AGBE suggested that the berry extract significantly reduced fasting hyperglycemia and body weight following a 12-day treatment (49,57). Ginsenoside Re was identified as an active anti-diabetic constituent in AGBE (58).

It is reported that oxidative stress was linked to diabetes (59–61). As a botanical anti-oxidant, American ginseng may protect against diabetes by contributing to the total anti-oxidant defense system of the human body (62,63). However, a recent study demonstrated that the anti-diabetic effects of American ginseng may not be linked to anti-oxidant activity (62).

Effects on Central Nervous System

Ginsenosides in American ginseng are responsible for its effects on the central nervous system (CNS) and the peripheral nervous system (64). Ginsenosides regulate various types of ion channels, such as voltage-dependent and ligand-gated ion channels, in neuronal and heterologously expressed cells. Ginsenosides inhibit voltage-dependent Ca^{2+} , K^{+} , and Na^{+} channel activities in a stereospecific manner (65). Ginsenosides also inhibit ligand-gated ion channels such as *N*-methyl-D-aspartate, some subtypes of nicotinic acetylcholine, and 5-hydroxytryptamine type 3 receptors. Competition and site-directed mutagenesis experiments revealed that ginsenosides interact with ligand-binding sites or channel pore sites and inhibit open states of ion channels. The effect of ginsenoside Rg₁ or Rb₁ was also examined and they both enhance CNS activities, but the effect of the latter is weaker (66), sometimes even having an inhibitory effect on the CNS. American ginseng has a lower ratio of Rg₁ to Rb₁ content. Thus, American ginseng is “cool” or calming to the CNS. The protective effects of Rb₁, Rg₁, Rg₃, and Rh₂ on neurodegeneration are well studied (64,67). Ginsenoside Rb₁ obtained from American ginseng roots was also shown to be able to partially prevent the memory deficits caused by the cholinergic agent scopolamine in a rat model (68).

Anti-cancer Effects

Effects of American ginseng on cancer treatment and side-effect management were evaluated. These observations include in vitro and in vivo anti-cancer activity alone and in combination with chemotherapy, potential mechanisms of action of anti-cancer effect, chemopreventive effect

supported by epidemiologic data, and effects on preventing or alleviating chemotherapy-induced side effects.

In *in vitro* studies, American ginseng extracts were found to inhibit the growth of breast cancer cells (69,70). Recently, our group observed that after steaming treatment of American ginseng, its antiproliferative effects were improved significantly, possibly due to the altered ginsenoside profile (38,36). In another study, the anticolorectal cancer effects of AGBEs were evaluated. In comparison to unsteamed extract, steamed extract showed significantly stronger antiproliferative effects on cancer cells. Antiproliferative effects of representative constituents were also evaluated showing that ginsenoside Rg₃ had a positive effect. Steamed American ginseng extract inhibited the colorectal cancer growth both *in vitro* and *in vivo*, and this inhibition might be achieved through cell cycle arrest and induced apoptosis in the cells (71). In addition, the extract from American ginseng enhanced the antiproliferation effect of cisplatin on human breast cancer cells, suggesting that ginseng possesses its own anti-cancer activity (72).

Additional studies suggested that American ginseng and its purified ginsenosides may inhibit cancer cell proliferation by inducing gene and protein expression of the cell cycle regulatory protein p21, thus arresting tumor cell cycle progression (73), by inducing cancer cell apoptosis through activation of caspase-3 protease via a bcl-2-insensitive pathway and by sensitizing multidrug-resistant tumor cells to chemotherapy (74,75). To further characterize downstream genes targeted by steamed American ginseng extracts in a human colorectal cancer cell line, the gene expression profiling was assayed. This interesting research work showed that the most affected pathway was the Ephrin receptor pathway. The top upregulated and downregulated genes were identified. This important knowledge could further be used to develop ginseng derivatives as novel chemotherapeutic and/or chemopreventive agents for human cancer (76).

For cancer chemoprevention, epidemiologic evidence based on a case-control study on over 1000 subjects in Korea showed that Asian ginseng users had a decreased risk for many different cancers compared with nonusers (77,78). Data suggested that ginseng has a nonorgan-specific preventive effect against cancer (79).

The commonly used cancer chemotherapies are still limited by severe side effects and dose-limiting toxicity. The drug-related adverse events not only worsen patients' quality of life, but can also lead to their refusal to continue the potentially curative chemotherapy. Our group investigated the effects of several herbal extracts on reducing chemotherapeutic side effects and found that American ginseng can attenuate cisplatin-induced nausea and vomiting in a rat model (80) without affecting its anti-cancer properties in human cancer cells (72).

Effects on Immune System

It is generally accepted that ginseng's anti-cancer effects should be linked to its activity with the immune system. Ginsenosides from American ginseng enhance the formation of antibodies and immune functions in cancer patients and in microbe-infected experimental laboratory animals,

possibly by elevation of the cyclic adenosine monophosphate (cAMP) levels. Both antitumoral activity and stimulation of the immune function have been observed in early experimental animals and in human subjects (81).

Ginsenosides Rb₂, Rc, and Rg₁ were subsequently confirmed as stimulants of DNA synthesis in bone marrow cells possibly by the involvement of cyclic nucleotides (82). Therefore, preparations of American ginseng may be useful in the prevention and treatment of hematopoietic damage induced by chemical agents. An *in vivo* study showed that total saponins of American ginseng partially restored the activity of cyclophosphamide-depressed bone marrow stem cell proliferation and splenocyte proliferation in mice and enhanced production of interleukin-3 (IL-3) and IL-6-like substances from the splenocytes (45). It may also oppose the depressant effects of cyclophosphamide and other chemotherapeutic agents on the bone marrow stem cell proliferation by control of hemopoietic growth factor production in the splenocytes (83).

A polysaccharide-rich extract of American ginseng showed a number of biological effects, including the enhancement of lymphocyte transformation, induction of interferon- γ (IFN- γ) and IL-1 production, and stimulation of spleen cell production of an IL-3-like cytokine activity (84). Recently, in comparison to American ginseng saponin extract, the effect of this polysaccharide-rich extract on systemic and gut-associated immune function was evaluated. Feeding the polysaccharide-rich extract modifies systemic immune responses and appears to affect gut-associated immunity in a manner distinct from that of saponin-containing extracts of American ginseng (85).

CLINICAL STUDIES

Cardiovascular System

Several beneficial effects on the cardiovascular system have been attributed to the use of American ginseng, thus proving its popularity as an alternative in cardiovascular therapeutics (47). In a randomized, double-blinded, placebo-controlled trial, 16 hypertensive individuals received 3 g of American ginseng powder or placebo. After treatment, blood pressure was measured every 10 minutes for 160 minutes. There was no difference in the effects of American ginseng and the placebo on the overall (160 minutes) mean blood pressure change of the individuals. Since an early observational study suggested that Asian ginseng could elevate blood pressure, the administration of American ginseng caused concern. This observation suggested that American ginseng exerts a neutral acute effect on blood pressure in hypertensive individuals (86).

In another double-blinded, placebo-controlled, crossover trial in 52 hypertensive individuals to determine the effect of 12-week American ginseng intake on 24-hour blood pressure, after a 4-week placebo run-in, 52 participants were randomly assigned to 3 g/day of American ginseng or placebo for 12 weeks. American ginseng did not affect the blood pressure or serum cystatin C level. This study suggested that long-term American ginseng use had no effect on 24-hour blood pressure and renal function in hypertensive individuals (87).

The effects of American ginseng powder (1.6 g/day) on physically active male college students who received

exhaustive running exercise compared with placebo in a four-week randomized study have been reported. According to this study, although there was no noticeable improvement in the 80% $\text{VO}_{2\text{max}}$ of the experimental group over the placebo group, the production of plasma creatine kinase during the exercise significantly decreased for the American ginseng group than for the placebo group. Administration of American ginseng for four weeks prior to exhaustive aerobic treadmill running reduced the leakage of creatine kinase during exercise, but did not enhance aerobic work capacity. The reduction of plasma creatine kinase may be due to the fact that American ginseng is effective for the decrease of skeletal muscle cell membrane damage, induced by exercise during the high-intensity treadmill run (88).

Diabetes

Historical records on traditional medicinal systems reveal that ginseng root was used to treat a disease corresponding to diabetes (89). Description of ginseng's medicinal effects found in the ancient Chinese *Materia Medica* contained a reference to ginseng's ability to "quench thirst," amongst the other wide-ranging beneficial effects (90). This effect, as per Traditional Chinese Medicine, could be related to the anti-diabetic activity of ginseng. Research on the effects of treatment with ginseng root on blood sugar levels started in the early part of the last century (91). Ginseng root has since been used to treat diabetic patients (90). Results of clinical trials support the claim that ginseng root possesses anti-diabetic properties.

Seven clinical studies using American ginseng as a potential therapy for diabetes were found. A double blind placebo-controlled study in which ginseng root tablets (100 or 200 mg daily for eight weeks) were orally administered to 36 newly diagnosed type II diabetic patients showed a reduction in fasting blood glucose and glycosylated hemoglobin (92). On the other hand, some clinical trials from the same group were examining the herb's short-term effects. Vuksan reported antihyperglycemic activity when a single dose of 3 g American ginseng root was administered in both nondiabetic and type II diabetic individuals (93). Other short-term metabolic trials in healthy volunteers also found decreases in postprandial glucose (94–98). The available evidence for American ginseng in diabetes suggests a possible hypoglycemic effect; however, the trials are small and longer-term studies are needed (99).

Respiratory Infection

In a randomized, double-blind, placebo-controlled study, 89 (2000, 8 weeks) and 109 (2000–2001, 12 weeks) enrolled older adults, average age 81 and 83.5, respectively, were orally administered a proprietary American ginseng extract, 200 mg or placebo (twice daily) during the influenza season. An intent-to-treat analysis of pooled data corrected for drug exposure time showed that the incidence of laboratory-confirmed influenza illness was greater in placebo- (7 cases/101 subjects) than American ginseng-treated (1/97) groups ($P = 0.033$). Combined data for laboratory-confirmed influenza illness and respiratory syncytial virus illness were also greater in placebo- (9/101) than American ginseng-treated (1/97) groups ($P = 0.009$),

for an overall 89% relative risk reduction of acute respiratory illness in the American ginseng group. American ginseng was shown to be safe, well tolerated, and potentially effective for preventing acute respiratory illness due to influenza and respiratory syncytial virus (100).

In another double-blind placebo-controlled study, at the onset of the influenza season, 279 subjects (18–65 years of age) with a history of at least two colds in the previous year were instructed to take 400 mg daily of either the American ginseng poly-furanosyl-pyranosyl-saccharide-rich extract or a placebo for a period of four months. Data from this study suggested that the American ginseng extract reduced the mean number of colds per person, the proportion of subjects who experienced two or more colds, the severity of symptoms, and the number of days with cold symptoms (101).

Anti-fatigue

To investigate whether American ginseng might help cancer-related fatigue, in a randomized double-blind study, 290 cancer patients received American ginseng in doses of 750, 1000, or 2000 mg/day or placebo given in twice daily dosing over eight weeks. Overall, this study suggested that American ginseng, at a dose of 750 mg/day, did not provide any benefit over that seen with a placebo. However, the two highest doses of ginseng (1000 and 2000 mg/day) did appear to decrease fatigue more than did a placebo, as measured by various scales of fatigue, vitality, and well-being. There were no significant toxicities apparent in the active arms compared to the incidences seen in those taking the placebo. This was true despite the fact that many of these participants had advanced disease and were taking cytotoxic treatment for their disease. Data suggested that the higher doses studied may be helpful in cancer-related fatigue (102).

Prescription Drug Interactions

In a case report, the anti-coagulant effect of warfarin decreased after patients consumed ginseng (103). To evaluate the interactions between American ginseng and warfarin, a randomized, double-blind, placebo-controlled trial was conducted (104). In this four-week study, 20 subjects received warfarin for three days during weeks 1 and 4. Beginning in week 2, patients were assigned to receive either American ginseng or placebo. The peak international normalized ratio (INR) statistically significantly decreased after two weeks of ginseng administration compared with placebo. The INR area under the curve (AUC), peak plasma warfarin level, and warfarin AUC were also statistically significantly reduced in the ginseng group as compared with the placebo group. Although the study sample consisted of young, healthy volunteers in a research setting rather than patients taking therapeutic doses of warfarin, American ginseng was found to reduce warfarin's anti-coagulant effect. Data from this study suggested that when prescribing warfarin, physicians should ask patients about ginseng use (104).

Recently, interaction of American ginseng with antiretroviral chemotherapies was evaluated. In a clinical study, 24 healthy volunteers received indinavir 800 mg every 8 hours for 3 days and then indinavir and American ginseng 1 g every 8 hours or placebo for 14 days.

Indinavir pharmacokinetics and insulin sensitivity were assessed before and after American ginseng coadministration. There was no difference in the area under the plasma concentration time curve after the coadministration of American ginseng, compared to indinavir alone. Although insulin-stimulated glucose disposal per unit of insulin (M/I) decreased, M/I remained unchanged after coadministration of indinavir and American ginseng. This data suggest that American ginseng did not significantly affect indinavir pharmacokinetics (105).

In another recent study, 10 healthy volunteers received 300 mg of zidovudine (an antiretroviral agent) orally before and after two weeks of treatment with a ginsenoside-enriched American ginseng extract 200 mg twice daily. Pharmacokinetic profiles of zidovudine and oxidative stress marker concentrations were measured post-zidovudine dose. Two weeks of American ginseng did not alter zidovudine pharmacokinetics but reduced oxidative stress markers (106). It appears that American ginseng did not affect these two antiretroviral agents' pharmacokinetics.

PHARMACOKINETICS AND METABOLISM

The pharmacokinetic data are unavailable when American ginseng extract is administered. The metabolism and pharmacokinetics of single compounds from American ginseng have been studied using rats, dogs, and humans.

The average half-life time of ginsenoside Rd in plasma was detected as 19.29 hours, when 10 mg of ginsenoside Rd was administered intravenously to the volunteers. Seven metabolites including three oxygenated, two combined, and two hydrolyzed components were identified in rat urine samples by using liquid chromatography-mass spectrometry (LC-MS) (107). Ginsenoside Re was rapidly cleared from the body with a short half-life (0.2 ± 0.03 hours for male and 0.5 ± 0.08 hours for female mice after i.v.) and oral absorption was generally poor (108). The observed oral bioavailability of ginsenoside Rh₂ was 17.6% and 24.8% for male and female dogs, respectively (109). The absolute bioavailability of 20(S)-ginsenoside Rh₁ in rats was only 1.01% (110).

When taken orally, protopanaxadiol-type ginsenosides are mostly metabolized by intestinal bacteria to a protopanaxadiol monoglucoside, 20-O-beta-D-glucopyranosyl-20(S)-protopanaxadiol (M1). In humans, M1 is detected in plasma 7 hours after the intake of ginsenosides and in urine 12 hours after the intake, indicating that M1 is the final metabolite of this type of ginsenoside (111). Ginsenoside Rb₁ was not detectable in serum for 24 hours, indicating a major intestinal bacterial metabolism (112). In vitro and in vivo experiments showed that CYP450-catalyzed mono-oxygenation, intestinal bacteria-mediated deglycosylation, and gastric acid-mediated hydration reaction were the main metabolic pathways of this compound (110).

DOSAGE AND SAFETY

- No dosage suggestion (*U.S. Pharmacopoeia-NF 2008*)
- Up to 6 g, not for long-term use (*Chinese Pharmacopoeia, 2005 Edition*)

As references, Asian ginseng dosage: 1 to 2 g of root per day for up to three months, and a repeated course is feasible (113). Based on *PDR for Herbal Medicines*, the average daily dosage of Asian ginseng is 1 to 2 g root, and may be taken three to four times a day over three to four weeks (114).

In China, doses have been given up to 50 g, and some large doses have resulted in insomnia, depression, and nervousness. Regarding the so-called ginseng abuse syndrome (115), most reported adverse effects were increased blood pressure, nausea, headache, insomnia, nervousness, and diarrhea. To avoid this syndrome, recommended doses to be therapeutically effective were as low as 0.5 g (115). As Siegel stated, this dose can be used in a wide variety of commercial ginseng preparations, including Asian ginseng or American ginseng (115).

Ginseng, Asian

Lee Jia and Fabio Soldati

INTRODUCTION

Recent revolutions in life science and technology including genomics, proteomics, nanotechnology, and highly sensitive chemical analysis methods have enriched our knowledge of *Panax ginseng* (*P. ginseng*; Fig. 1) and improved our understandings of this traditional herb medicine. The newly isolated and characterized chemical entities from *P. ginseng* added many new members to ginseng species. Preclinical in vitro and in vivo tests on the active ingredients of this species discovered some previously unknown biological functions of those ingredients. This review covers etymology and history of *P. ginseng*, the ways to cultivate and process it, and the related cookery. The review also lists ginseng's active ingredients (i.e.,

mainly ginsenosides) and standardized analytical methods used for quality control of various ginseng products as well as relevant government regulations. The active and inactive chemical entities obtained from *P. ginseng* can be classified into five categories that are saponins, polysaccharides, polyynes, flavonoids, and volatile oils. The recent preclinical findings of pharmacological effects of *P. ginseng* are narrated herein with critical discussions. These new findings include effects of ginseng on upregulating biological production of nitric oxide, which result in its aphrodisiac effect and cardiovascular effect; its anti-hyperglycemic effect that may benefit type II diabetics as evidenced by in vitro and in vivo studies using β -cells and obese diabetic mouse models; its neuropharmacological effect and its roles in cancer treatment. We also summarized pharmacokinetics and metabolism profiles of active ginseng ingredients, and analyzed its safety test results obtained from ginseng extract or ginsenosides. Various human clinical trials to test ginseng effectiveness on diabetics, psychophysiological performance, immunomodulation, and others are also discussed followed by information on ginseng overdose and drug interactions.

ETYMOLOGY AND HISTORY

The English word "ginseng" derives from the Chinese term "rénshēn" (simplified: 人参; traditional: 人蔘), literally "man root" (referring to the root's characteristic forked shape, resembling the human body and the legs of a man). The current Japanese word for "ginseng" is 人参, or "ninjin" meaning carrot, or "chosen ninjin," adopting the name of ninjin from the last dynasty of Korea (Choson). The Korean name of ginseng is 高麗人蔘, or "goryo insam."

Ginseng refers to the root of several species in the plant genus *Panax* (C.A. MEYER Araliaceae). The botanical name "*Panax*" was given by the Russian botanist Carl Anton von Meyer (1795–1855) in 1843 in the Bulletin of Physics and Mathematics published by the Academy of Petersburg Institute(1). In Greek, "pan" means all and "axos" means cure. *Panax* was applied to this genus after Carl Linnaeus was aware of its wide use in Chinese medicine. Carl Linnaeus (1707–1778, Swedish) had introduced over 9000 binomial names for both plants and animals. The earliest record of ginseng in Europe goes back to 1711 when a Jesuit, Father Jartoux, who worked in Chinese missions, sent a letter to the general procurator in Paris, describing this plant, which he had never seen before, as having immense therapeutic properties. The ginseng plant then remained practically unknown to the scientific Western world until the early 1960s when researchers

Figure 1 A typical *Panax ginseng*.

started to investigate its pharmacological and therapeutic properties. One of the major difficulties was the lack of demonstration of its healing power following protocols accepted by Western medicine (2).

Among them, *Panax ginseng* (*Panax ginseng* C.A. Meyer) is the most widely used ginseng and is indigenous to the Far East countries, most notably China and Korea (2). Cultivation of *P. ginseng* began at around 11 BC and has a medical history of more than 2000 years (3).

CULTIVATION AND PROCESSING

Ginseng grows in the Northern Hemisphere, typically in cooler climates. They are slow-growing perennial plants with fleshy roots (4,5). The plant grows 6 to 18 in. tall with 1 to 3 umbels of 15 to 30 flowers and greenish-yellow corollas. The fruit is a pea-sized, globular to reniform, scarlet, smooth, and glossy drupe, which contains two seeds (6). The plant usually bears three leaves, each with three to five leaflets 2 to 5 in. long. In China, Korea, Japan, and Russia, the cultivated ginseng roots are harvested when the plant is 3- to 6-year-old. The treasured aromatic root resembles a small parsnip that forks as it matures. It should be noted that ginseng is not derived from the rhizomes (the thick stem that lies flat along the ground with roots and leaves growing from it).

There are two different ways of processing ginseng after harvest: air drying and steaming the roots; the former results in white ginseng and the latter produces red ginseng. In Asia, the roots (which in nature are white) are sometimes treated with steam at approximately 100°C for differing times in order to protect them from microbiological pathogens. This high-temperature treatment results in the reddening of the epidermis of the roots producing the so-called "red ginseng." Not only are the sugars in the epidermis of the root caramelized by the heating, but the ginsenosides are also partially chemically modified and/or destroyed (7). In addition, the distribution of the ginsenosides is different in the various parts of the plant, both in total content and in the relative ratio of the different ginsenosides.

Ginseng cultivated in Korea is classified into three types, depending on how it is processed: fresh ginseng (less than 4 years old), white ginseng (4–6 years old and dried after peeling), and red ginseng (harvested when 6 years old, steamed and dried) (8). Red ginseng is not skinned before it is steamed or otherwise heated and subsequently dried. In the course of the steaming process, ginseng starch is gelatinized, causing an increase in saponin content. Traditionally red ginseng has been used to restore and enhance normal well-being, and is often referred to as an adaptogen.

COOKERY

The fresh root, after peeled, can be directly chewed, or soaked in various wines for a period of time before drinking and chewing. Ginseng is most often available in dried form, either in whole or sliced form. Ginseng leaf, although not as highly prized, is also used; as with the root it is most often available in dried form. The correct and

efficient cooking processes for the dried ginseng are as follows: washing the dried roots with running water; immersing the dried roots in boiled water and maintaining the roots in hot water for at least three hours or overnight; taking the soaked and hence soft roots out of water and slicing the roots with a knife as thin and small as possible; and finally stewing the sliced roots slowly and gently in water in a closed vessel before drinking all extracted liquid.

Ginseng is usually sliced and simmered in hot water to make a decoction. Ginseng ingredient may also be found in some popular energy drinks, tea varieties, or functional foods. Ginseng root is often sliced and steamed with chicken meat as a soup in China (including Taiwan) and Korea. Usually ginseng is used at subclinical doses for a short period and as such, it does not produce measurable medicinal effects. Daily consumption of ginseng root varies individually from 2 to 20 g depending on whether hypertension or high heart rate occurs at a given dose.

GINSENOSES: CHARACTERISTIC INGREDIENTS

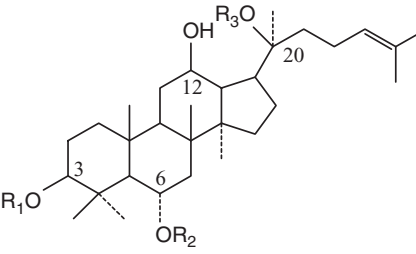

Ginseng is characterized by the presence of ginsenosides. Ginsenosides are triterpenes saponins considered to be the main bioactive principles of ginseng (Fig. 1). The content of ginsenosides and their metabolites varies depending on the *Panax* species, the plant age, the part of the plant, the preservation method, the season of harvest, and the extraction method (9,10). The ginsenoside content variability can also be in part ascribed to differing growth conditions, such as kind of soil, weather conditions, geographical location, and different production procedures. Table 1 lists various concentrations of ginsenoside and its metabolites that develop in complexity with age of ginseng (11). Soldati and Tanaka (12) also documented a relationship between the age of the plant and the content of ginsenosides: the major development of the roots occurs between the fourth and fifth year of growth, during which time the root doubles its weight, and the optimum yield of ginsenosides occurs at the fifth year.

Total ginsenosides content in *P. ginseng* varied from 0.2% to 2% for main roots and from 4% to 9% for root hair. Although the main source of ginsenosides is from ginseng root, the leaf, stem, and berry parts of ginseng also contain significant quantities of ginsenosides (13).

STANDARDIZED EXTRACTION AND QUALITY CONTROL

The U.S. Pharmacopoeia gives a detailed description of the quality of a standardized Asian ginseng extract: "Powdered Asian Ginseng Extract is prepared from Asian Ginseng by maceration, percolation, or both processes performed at room temperature with suitable solvents such as alcohol, methanol, water, or mixtures of these solvents, and by concentrating the fluid extract at temperatures below 50°. The ratio of the starting crude plant material to Powdered Extract is between 3:1 and 7:1. It contains not less than 3.0 per cent of ginsenosides Rg₁, Re, Rb₁, Rc, Rb₂, and Rd combined, calculated on the anhydrous basis. It may contain other added substances." Moreover, the

Table 1 Structures of 7 Ginsenosides Commonly Used for Quality Control of Ginseng Products

				ST AN DA RD IZ ED EX TR AC TI ON
R1	OR2	R3		
Rb1	Glucose-2→1-glucose	2H	Glucose-6→1-glucose	
Rb2	Glucose-2→1-glucose	2H	Glucose-6→1-arabnose(pyr)	
Rc	Glucose-2→1-glucose	2H	Glucose-6→1-arabnose(fur)	
Rd	Glucose-2→1-glucose	2H	Glucose	
Re	H	O-glucose-2→1-rhamnose	Glucose	
Rf	H	O-glucose-2→1-glucose	H	
Rg1	H	O-glucose	Glucose	

USP gives detailed information on the methods for identification [thin layer chromatography (TLC)] and content determination [high-performance liquid chromatography (HPLC)] of the ginsenosides as well as limits for microbial contamination, water, pesticide residuals, heavy metals, organic volatile impurities, and alcohol content (14).

HPLC methods developed for the quantification of ginsenosides contained in the roots and in the finished products are also included in the U.S. Pharmacopoeia and European Pharmacopoeia for the definition of *P. ginseng* roots and *P. ginseng* extracts. Ginseng species were well described in the Chinese Pharmacopoeia when the second edition of the Pharmacopoeia was published in 1963, and the information is periodically updated to the current seventh edition, including the methods used for the quantification of ginsenosides.

According to the U.S. Pharmacopoeia published monographs, *P. ginseng* roots are defined to contain not less than 0.2% Rg₁ and 0.1% Rb₁ and *P. ginseng* extract, contains not less than 3.0% ginsenosides, calculated as the sum of ginsenosides Rb₁, Rb₂, Rc, Re, Rg₁, and Rd and determined by HPLC-UV. European Pharmacopoeia published a monograph on *P. ginseng* roots in which the content of ginsenosides Rb₁ and Rg₁, determined by HPLC-UV, is not less than 0.4%; moreover, the peak due to the ginsenoside Rf is present in *P. ginseng* roots (in case of a substitution with *P. quinquefolium* no peak due to ginsenoside Rf is present) (15). Concerning the literature data, besides the natural variation due to the heterogeneity of the plant material, the main reason of this variability of ginsenosides content is attributable to the choice of the compounds to be quantified in ginseng. Some authors quantified neutral ginsenosides Rb₁, Rb₂, Rc, Re, Rg₁, and Rd stating that they make up 90% of total saponin content (16). However, other authors showed that the content

of acidic saponins malonyl-ginsenoside Rb₁, Rb₂, Rc, and Rd represents between 35% and 60% of the total content of ginsenosides in both *P. ginseng* and *P. quinquefolius* (17). Since malonyl-ginsenosides are likely to release ginsenosides upon consumption of ginseng products, the content of sole neutral saponins may not reflect the potency of the product. Furthermore, the relative contents of acidic and neutral ginsenosides could be used for the determination of the age and the processing of ginseng samples (Table 1). In fact the malonyl-ginsenosides Rb₁, Rb₂, Rc, and Rd are quite unstable, difficult to be isolated and degraded to the corresponding ginsenosides Rb₁, Rb₂, Rc, and Rd during steaming (Red ginseng) or extraction at temperatures above 70°C (158°F). This is the reason why Pharmacopoeias do not include such compounds as reference standards in the Radix ginseng monographs. Some companies for marketing reasons increase “artificially” the genuine content of the ginsenosides by heating the roots or extracting them at high temperatures.

In order to evaluate the quality of the products on the U.S. market, the American Botanical Council started the Ginseng Evaluation Program (GEP) in 1993 (18). The GEP is an analytical evaluation that measures product content and consistency, and compares these to the label claims. The GEP developed and validated testing methodologies for consumer products, and analyzed more than 500 *P. ginseng* (*P. quinquefolius* and *Eleutherococcus senticosus*) products using HPLC to profile and assay ginsenosides (and/or eleutherosides), for the full text of the methodologies used by the GEP, please refer to www.herbalgram.org. The identities of the reference ginsenosides (and eleutherosides) were determined by spectroscopic means (nuclear magnetic resonance, liquid chromatography/mass spectrometry, LC/MS), and their purity was established by HPLC analysis (19). Of the

numerous ginsenosides that have been identified from ginseng, Rb₁, Rb₂, Rc, Rd, Re, and Rg₁ have been chosen for reference standards for ginseng products (20). However, the GEP evaluated quality of ginseng products by testing for the presence and amount of seven major ginsenosides Rb₁, Rb₂, Rc, Rd, Re, Rf, and Rg₁ (19) (Table 1). Each product was evaluated for lot-to-lot consistency as demonstrated by the following three factors: 1% of lots with an Rb₁/Rg₁ ginsenoside value within an acceptable range for *P. ginseng*; 2% of lots that met claim for total ginsenoside content; and 3% relative standard deviation (%RSD) of the lot-to-lot total ginsenoside content.

GINSENG PRODUCT REGULATIONS

In China, there are more than 900 ginseng-related products registered to the Chinese State Food and Drug Administration (SFDA, www.sfda.gov.cn) as a kind of Chinese medicinal formula that contains different amounts of ginseng and its ingredients. These products are formulated as extract, compounded extract, or tincture of ginseng root, capsules containing extract of ginseng root or leaves, and ginsenosides. In addition, there were 46 types of food products containing ginseng and its extracts under the SFDA inspection.

In United States, the Center for Food Safety and Applied Nutrition of the U.S. Food and Drug Administration (FDA) monitors ginseng quality and safety. According to federal regulations, products making claims fall into two classes. Class I refers to manipulated products (e.g., standardized ginseng extract) or products containing added ingredients (e.g., softgels containing standardized ginseng extract). These products must contain at least 100% of the claim throughout the shelf life of the product. Thus, an Asian ginseng product standardized to 4% ginsenosides must contain at least 4% ginsenosides throughout the shelf life of the product. Class II refers to naturally occurring, nonmanipulated ingredients (e.g., Asian ginseng root powder). These products must contain at least 80% of the claimed amount of the specified ingredient over the shelf life of the product [Code of Federal Regulations 21 CFR101]. If an Asian ginseng root powder product claims 4% ginsenosides, then that product must contain at least 80% of 4% (i.e., 3.2%) for the shelf life of the product.

GENERAL CLASSIFICATION OF GINSENG INGREDIENTS

The detailed chemical structures and related bioactivities of more than 100 chemical entities of ginseng can be found in the recent report (21). So far, approximately 200 substances have been isolated and characterized from *P. ginseng*, both from primary and secondary metabolism of the plant. These include 30 ginsenosides, 40 ether-soluble compounds, 8 nitrogen-containing compounds, 32 volatile compounds, 13 carbohydrates/polysaccharides, 9 glycanes, 56 lipids and fatty acids, and 9 trace elements. The ginsenosides are characteristic substances of ginseng (11). In general, active or inactive chemical entities obtained from ginseng species can be classified into five categories

ranked below in the order of their bioactivities: saponins, polysaccharides, polyynes, flavonoids, and volatile oils.

1. Saponins (or sapogenin glycosides). Saponin is a type of glycoside that is widely distributed in plants. Each saponin consists of a sugar and a sapogenin, the latter constitutes the aglucon moiety. The sapogenin may be a steroid or a triterpene. The sugar moiety may be a glucose, maltose, fructose, galactose, pentose, or methylpentose. Ginseng's saponins are generally called ginsenosides (Rx), which are considered as the main active principals of ginseng and often used as a marker for the quality control of ginseng drugs and commercial products. The basic structure of ginsenosides is similar. They consist of a gonane steroid nucleus with 17 carbon atoms arranged in four rings. The characteristic biological responses for each ginsenoside are attributed to the differences in the type, position, and number of sugar moieties attached by the glycosidic bond at C-3, C-6, and C-20 (3,11,22). Ginsenosides are amphipathic in nature. The hydroxyl (OH) group of ginsenosides allows both interactions between the polar head of the membrane phospholipids and the β -OH group of cholesterol, while the hydrophobic steroid backbone can interact with the hydrophobic side chains of fatty acids and cholesterol. Indeed, these physiochemical interactions are greatly determined by the numbers and sites of polar hydroxyl groups on each ginsenoside. Up to now more than 100 ginsenosides have been isolated from *Panax* species and most of them exhibit four types of aglycone moieties:

- Protopanaxadiol [or aglycone (20S)-protopanaxadiol]: dammarane-type ginsenosides including ginsenosides Ra₁, Ra₂, Ra₃, Rb₁, Rb₂, Rb₃; notoginsenoside R₄, Rs₁, Rs₂, Rs₃, Rs₄; and malonyl-ginsenoside Rb₁, Rb₂, Rc, and Rd. The metabolism pathway of the protopanaxadiol has been extensively investigated resulting in identification and characterization of several active metabolites.
- Protopanaxatriol [or aglycone (20S)-protopanaxatriol]: also dammarane-type ginsenosides including ginsenosides Re, Rf, Rg₁, and notoginsenoside R₁. The main structural difference between protopanaxatriol and protopanaxadiol is that the latter holds only H element at C6.
- Oleanolic acid (or aglycone oleanolic acid): including ginsenosides Ro that is an oleanane triterpenoid, chikusetsusaponin-V Rb₁, Rb₂, Rc, Rd, Re, and Rg₁.
- Ocotillol type.

2. Polysaccharides: These are water soluble and include panaxane A to U. The acidic polysaccharides (MW 10,000–150,000 Da) have immunomodulating and antiproliferative effects. They contain various sugar moieties, uronic acid, and less than 5% protein by weight. Recent studies have identified an acidic polysaccharide, referred to as "Ginsan," with noted immunostimulatory activity (23,24).
3. Polyynes: The polyynes are a group of organic compounds with alternating single and triple bonds. The term polyyne simply implies the presence of several alkynes. In ginseng, these include falacrinol

(panaxynol), falcarintriol (panaxytriol), acetic acid or linolenic acid.

4. Flavonoids
5. Volatile oils: Qiu et al. (25) recently used comprehensive two-dimensional gas chromatography/time-of-flight MS or flame ionization detector to characterize and quantify the chemical composition of volatile oil in the radices of *P. ginseng* harvested from Changbai Mountain in Jilin province, China. These ginseng samples were 3, 5, and 8 years old, respectively. They tentatively identified total 36 terpenoids in the ginseng volatile oil based on the mass library search and retention index of each oil entity. The study found that the following components of the volatile oil significantly increased with the age of the ginseng: α -cadinol, α -bisabolol, thujopsene, and *n*-hexadecanoic acid.

Four malonyl derivatives of ginsenosides Rb₁, Rb₂, Rc, and Rd were well described by Fuzzati (26). The malonyl derivatives and ginsenoside Ro (an oleanane-type triterpenoid) are also called "acidic" ginsenosides while the other are usually named "neutral" ginsenosides. Due to the fact that ginseng is a very popular phyto-medicine used all over the world, a huge quantity of work has been carried out during the last 30 years in order to develop analytical methods for the identification, quantification, and quality control of ginsenosides in raw plant materials, extracts, and marketed products. One of the main goals of these researches was to differentiate the ginsenosides pattern between the different *Panax* species in order to avoid adulteration or misidentification. Moreover, studies of changes in ginsenosides composition due to different traditional processing of *P. ginseng* roots such as white and red ginseng have been undertaken.

PRECLINICAL STUDIES

Ginseng is mainly used, as it has been for hundreds of years, to increase resistance to physical, chemical, and biological stress and boost general vitality. In addition, we have begun to recognize its newly found activities, including antihyperglycemic effect that may benefit type II diabetics, its modulation to immune system that may serve as an immunotherapeutic agent for combination with chemotherapy.

Glucose Metabolism and Diabetes Mellitus

Ginseng is one of the most studied anti-diabetic herb (27). Ryu et al. (28) investigated the anti-oxidant activity of Korean red ginseng and its effect on erectile function in noninsulin-dependent diabetes mellitus (NIDDM) rats induced by intraperitoneal injection of 90 mg/kg of streptozotocin on day 2 after birth. According to the diabetic period, the rats were classified as either short-term (22 weeks) or long-term (38 weeks) diabetics. The rats were fed 30 mg/kg of Korean red ginseng three times per week for one month. For those rats treated with Korean red ginseng, their erectile function and levels of glutathione (used as an index of the free radical-scavenging activity) (29) and malondialdehyde (an end product of lipid peroxidation used as an index of oxidative stress) were comparable to their age-matched normal controls. In con-

trast, the untreated diabetic rats showed impaired erectile function and increased levels of glutathione and malondialdehyde. Compound K, a major intestinal metabolite of ginsenosides derived from *P. ginseng*, exhibited antihyperglycemic effect through its insulin-secreting action, similar to that of insulin secretagogue sulfonylureas. Treatment of diabetic db/db (db: dependent diabetes) mice (type II diabetic model) for eight weeks with compound K (10 mg/kg), or combined with metformin resulted in significant improvements in plasma glucose and insulin levels (30).

A very interesting study showed antihyperglycemic and antiobese effects of *P. ginseng* berry extract and its major constituent, ginsenoside Re, in obese diabetic C57BL/6J ob/ob mice and their lean littermates (31). The animals received daily intraperitoneal injections of *P. ginseng* berry extract for 12 days. On day 12, 150 mg/kg extract-treated ob/ob mice became normoglycemic and had significantly improved glucose tolerance. The overall glucose excursion during the two-hour intraperitoneal glucose tolerance test decreased by 46% ($P < 0.01$) compared with vehicle-treated ob/ob mice. The improvement in blood glucose levels in the extract-treated ob/ob mice was associated with a significant reduction in serum insulin levels in fed and fasting mice. A hyperinsulinemic-euglycemic clamp study revealed a significant increase in the rate of insulin-stimulated glucose disposal in treated ob/ob mice. In addition, the extract-treated ob/ob mice lost a significant amount of weight associated with a significant reduction in food intake and a very significant increase in energy expenditure and body temperature. Treatment with the extract also significantly reduced plasma cholesterol levels in ob/ob mice. Additional studies demonstrated that ginsenoside Re plays a significant role in antihyperglycemic action. This anti-diabetic effect of ginsenoside Re was not associated with body weight changes, suggesting that other constituents in the extract have distinct pharmacological mechanisms on energy metabolism. Ginseng decreases acute postprandial glycemia (32).

Cardiovascular Effect

Ginseng has been shown to produce a number of actions on the cardiovascular system. Intravenous administration of ginseng to anesthetized dogs resulted in reduction, followed by an increase in blood pressure, and transient vasodilatation (33). Recent studies found close relationship between ginseng's effects and the NO production pathway, including regulation of cGMP and cAMP levels (34).

Korean red ginseng can improve the vascular endothelial dysfunction in patients with hypertension possibly through increasing NO (35). In addition to endothelium-derived NO release, Li et al. (36) reported that ginsenoside-induced vasorelaxation involves Ca²⁺ activated K⁺ channels in vascular smooth muscle cells. It has also been reported that crude saponin fractions from Korean red ginseng enhanced cerebral blood flow in rats (37), and ginsenosides reduced plasma cholesterol levels and the formation of atheroma in the aorta of rabbits fed on a high cholesterol diet (38). This antiatherosclerotic

action of ginseng components is apparently due to the correction in the balance between prostacyclin and thromboxane, inhibition of 5-hydroxytryptamine (5-HT) release, and adrenaline and thrombin-induced aggregation of platelets, regulation of cGMP and cAMP levels, and prolongation of the time interval between conversion of fibrinogen to fibrin. Also, ginsenosides have been shown to be relatively potent platelet-activating factor antagonists (39).

In parallel with these findings, Nakajima et al. (40) concluded that red ginseng was found to promote the proliferation of vascular endothelial cells, to inhibit the production of endothelin (that is known to constrict blood vessels and result in raising blood pressure), and to increase the production of interleukin-1 beta (IL-1 β), which suppresses the formation of thrombin in blood coagulation. The role of ginseng in angiogenesis has also been reported. For instance, Kim et al. (41) demonstrated that water extract of Korean red ginseng stimulated in vitro and in vivo angiogenesis via activation of phosphorylation of extracellular signal-regulated kinases 1 and 2 (ERK1/2), phosphatidylinositol 3-kinase (Akt), and endothelial nitric oxide synthase (eNOS) resulting in an increase in NO production (41). Ginsenoside Rg₁ promoted functional neovascularization into a polymer scaffold in vivo and tubulogenesis by endothelial cells in vitro (42). Therefore, ginsenoside Rg₁ might be useful in wound healing as it can induce therapeutic angiogenesis.

Neuropharmacology

Recently, it has been shown that ginseng and its components, ginsenosides, have a wide range of actions in the central nervous system (43). These effects include protective effects of ginsenosides against homocysteine-induced excitotoxicity, increased cell survival, extension of neurite growth, and rescuing of neurons from death in consequence of different insults either in vivo or in vitro. Ginseng roots appeared to be able to facilitate survival and neurite extension of cultured cortical neurons (44), and ginsenosides Rb₁ and Rg₃ protected neurons from glutamate-induced neurotoxicity. Following forebrain ischemia in gerbils, Wen et al. (45) demonstrated that central infusion of ginsenoside Rb₁ rescued the hippocampal CA1 neurons against lethal damage of cellular hypoxia.

Using a spinal neuron model, ginsenosides Rb₁ and Rg₁ proved to be potentially effective therapeutic agents for spinal cord injuries as they protected spinal neurons from excitotoxicity induced by glutamate and kainic acid and oxidative stress induced by hydrogen peroxide (46). The most recent studies further confirmed that Rg₁ and Rb₁ could enhance glutamate exocytosis and release in rat nerve terminals through affecting vesicle mobilization and activation of protein kinase A and/or C, respectively, resulting in an increase in synaptic vesicle availability (47).

Although the processes and mechanisms underlying the neuroprotective effects of ginseng upon dopaminergic neurons remain to be elucidated, several reports demonstrated the inhibition of ginseng on MPP⁺-(1-methyl-4-phenylpyridinium) uptake in dopaminergic neurons, the suppression of oxidative stress induced by auto-oxidation of dopamine, the attenuation of MPP⁺-induced apoptosis, and the potentiation of nerve growth factor (NGF). It has

been shown that certain ginsenosides inhibit dopamine uptake into rat synaptosomes, and consequently, provide protection against MPP⁺ through blockade of its uptake by dopaminergic neurons (48). Ginsenoside Rg₁ was shown to interrupt dopamine-induced elevation of reactive oxygen species (ROS) or NO generation in pheochromocytoma cells (PC12). *P. ginseng* attenuated MPP⁺-induced apoptosis as it decreased the intensity of MPP⁺-induced DNA laddering in PC12 cells and ginsenoside Rg₁ had protective effects against MPTP-induced apoptosis in the mouse substantia nigra. These anti-apoptotic effects of ginseng may be attributed to the enhanced expression of Bcl-2 and Bcl-xl, reduced expression of bax and nitric oxide synthase (NOS), and inhibited activation of caspase-3. Ginseng may also reverse the neurotoxic effects of MPP⁺ through elevation of NGF mRNA expression (48). In accordance, ginsenosides Rb₁ and Rg₁ elevated NGF mRNA expression in rat brain and potentiated NGF-induced neurite outgrowth in cell culture. Furthermore, it has been reported that ginsenosides Rb₁, Rg₁, Rc, and Re inhibited tyrosine hydroxylase activity and exhibited antidopaminergic action since they reduced the availability of dopamine at presynaptic dopamine receptors (49).

Long-term oral consumption of ginsenosides prevents memory loss in aged SAMP8 mice (a model of accelerated senescence that was established through phenotypic selection from a common genetic pool of AKR/J strain of mice) by decreasing oxidative stress and upregulating the plasticity-related proteins in hippocampus (50).

Immunology

The effect of oral administration of a standardized ginseng extract to mice for four consecutive days (10 mg/day) on immune response was investigated. The extract enhanced antibody plaque-forming cell response and circulating antibody titer against sheep erythrocytes. This finding was confirmed by oral administration of an extract with defined ginsenoside content to mice at doses of 10, 50, or 250 mg/kg body weight daily for five to six days, which resulted in enhanced immune responses in a battery of six ex vivo tests including primary and secondary immune responses against sheep red cells, natural killing activity, mitogen-induced proliferation, interferon production, and T-cell-mediated cytotoxicity (51). A standardized extract from ginseng roots and several fractions of the extract were found to possess anti-complement and mitogenic activities in mice spleen cell cultures, with the strongest anti-complement activity being observed in the crude polysaccharide fraction. The polysaccharide with the major anti-complement activity consisted of arabinose, galactose, and glucose, and small amounts of galacturonic acid, glucuronic acid, and rhamnose. Its molecular weight was estimated to be 3.68 – 105 kDa (52). An acidic polysaccharide fraction containing galactose, arabinose, and uronic acids showed inhibition of *Helicobacter pylori*-induced hemagglutination with a minimum inhibitory concentration of 250 mg/mL. Digestion of the fraction with pectinase resulted in a lower molecular weight oligosaccharide fraction, which was noninhibitory at a concentration of 4 mg/mL (53). A high output of inducible nitric oxide synthase (iNOS) was shown in mice

administered intraperitoneally with the acidic polysaccharide from ginseng. Newly synthesized iNOS protein was also observed in peritoneal macrophages cultured with interferon- λ and the acidic polysaccharide. Spleen cells from acidic polysaccharide-treated mice did not proliferate in response to concanavalin A, but responsiveness was restored by the cotreatment of NG-monomethyl-L-arginine (NMMA) with concanavalin A. The treatment of mice with aminoguanidine, a specific iNOS inhibitor, alleviated the acidic polysaccharide-induced suppression of antibody response to sheep red blood cells. Present results suggest that the immunomodulating activities of the acidic polysaccharide were mediated by the production of NO (54).

It was demonstrated that *P. ginseng* extract and purified ginsenosides exert an adjuvant effect on the immune responses against porcine parvovirus, Erysipelothrix rhusiopathie, and against Staphylococcus aureus in dairy cattle (55).

Innate immunity is the front line host defense that acts within minutes of infection to counter invasion by microorganisms. Members of the toll-like receptor (TLR) family recognize conserved pathogen-associated molecular patterns of virus, bacteria, fungi, and parasites. A *P. ginseng* extract administered orally to mice was able to modulate proinflammatory cytokine production throughout the increase of macrophage toll-like receptor 4 expression during physical stress (56).

Ginseng in Cancer Treatment

Although there is no conclusive evidence that ginseng itself can cure cancer, it makes sense that use of ginseng for cancer therapy should focus on synergistic combinations or palliative treatment. During active cancer therapy, ginseng should generally be evaluated in combination with chemotherapy and radiation. In this role, it acts as a biological response modifier and an adaptogen to synergistically enhance efficacy of the conventional therapy (57). It can improve immune system activity of patients and their appetite, and functions as a supplementary agent of chemotherapy. For instance, Xing et al. (58) treated 35 rectal cancer patients with retention enema containing 85% ginsenoside for four to six hours per day for six to eight consecutive days before surgical operation. The control group ($n = 15$) received retention enema containing saline in the same way. They reported that after ginsenoside treatment symptoms such as frequent defecation, hematochezia, and tenesmus were palliated in most patients (25 out of 35), and abdominal pain was relieved in 7 patients with incomplete intestinal obstruction. Electron microscopic examination showed apoptosis in 23 treated patients. In comparison, the above-mentioned changes were not observed in the control group. Preclinical studies have showed some immune-stimulating activity of ginseng and ginsenosides (59).

Recent in vitro experimental studies have showed anti-cancer effects of various ginsenosides that will be narrated below. However, we have to point out that these in vitro studies, although inexpensive to carry out, should only serve as an adequate screening mechanism, or help us understand the mechanisms of actions of ginsenosides. In addition, the concentrations of ginsenosides applied in

some in vitro experiments are as high as 100 μ M level in order to produce some biological effects. This fact suggests that the observed biological effects of ginsenosides are not specific to a particular pathway. Therefore, we propose that when a difference arises between in vitro and in vivo findings, the in vivo results should always take precedence over in vitro studies.

Rg₃ is one of the most effective cytostasis ginsenosides separated from ginseng. Rg₃ inhibits human prostate cancer cells and other androgen-dependent cells from proliferating (60). The mechanisms of actions of Rg₃ include (i) decreasing genetic expression of 5 α -reductase, (ii) inhibiting cell cycle evolution genes such as proliferating cell nuclear antigen gene and cell cycle protease D1 gene that would stop cells from proliferating, (iii) increasing cyclinase suppressor genes such as p21 and p27 so as to make cells arrest at G1 stage, (iv) downregulating Bcl-2 (the anti-induction apoptosis gene), and (v) activating caspase-3 (the induction apoptosis gene) to induce cell death. Rg₃ inhibited tumor cell proliferation and induced cell apoptosis in mice with induced liver cancer (61). In addition, Rg₃ can affect the differential expression of cell signaling genes and other related genes in human lung adenocarcinoma cell line A549, and induce apoptosis in the A549 tumor cells and HUVEC 304 cell lines. It was showed that Rg₃ and Rg₅ had significant inhibition on benzo(a)pyrene-induced adenocarcinoma (62) and dimethylbenz(a)anthracene (DMBA)-induced lung tumor in mice. The ginsenosides had strong inhibitory effects on the development of rat mammary adenocarcinoma induced by methyl-N-nitrosourea and N-ethyl-N-nitrosourea administration, as well as on DMBA-induced uterine and vaginal tumors (63). Using athymic mice transplanted with ovarian SKOV-3 cancer cells, Xu et al. (64) showed that intraperitoneal injection of ginsenoside Rg₃ alone, or Rg₃ combined with cyclophosphamide to the mice for 10 days improved life quality and survival of the mice, and reduced tumor weight in the mice in comparison to the control untreated mice. Chen et al. (65) reported that Rg₃ produced apoptosis in human bladder transitional cell carcinoma cell line EJ at IC₅₀ 125.5 μ g/mL after 48 hours of incubation. When treated with 150 μ g/mL of Rg₃ for 24 hours and 48 hours, the cells showed significant DNA ladders and apoptotic morphological characteristics including condensed chromatin, nuclear fragmentation, apoptotic bodies, and bright fluorescent granules as well as a higher caspase-3 expression. When the cells were treated with 75 μ g/mL of Rg₃ for 24 hours and 48 hours, or 150 μ g/mL of Rg₃ for 48 hours, the percentage of cells in S phase and G2/M phase was increased, whereas the percentage of cells in G0–G1 was decreased.

Ginsenoside Rh₂ induced apoptosis in various tumor cells by different pathways. Rh₂ interfered with B-cell lymphocyte/leukemia-2 (Bcl-2) family proteins-related apoptosis and activated protein kinase caspase-3 to cause cell apoptosis. Rh₂ induced apoptosis of rat C6Bu-1 glioma cells and human SK-N-BE(2) neuroblastoma cells through protein kinase C pathway. Ginsenoside Rh₂ also induced apoptosis in human malignant melanoma, which was partially dependent on caspase-8 and caspase-3 (66). Ginsenoside Rh₂ induced apoptosis and inhibited cell growth in C6 glioma cells, human lung adenocarcinoma A549 cells, and various ovarian cancer cell lines (67). Mediating G1

growth arrest and apoptosis in human lung adenocarcinoma A549 cells appeared to be the molecular mechanisms of ginsenoside Rh₂. Rh₂ inhibited human hepatoma Bel-7404 cell lines via arresting cell cycle, upregulating Bax protein expression, and downregulating mutated p53 protein expression. Rh₂ inhibited the growth of MCF-7 cells by inducing p21 protein expression and reducing cyclin D levels. As a result, cyclin/Cdk complex kinase activity, pRb phosphorylation, and E2F release could be inhibited.

Another ginsenoside, that is, compound K (or IH901), was shown to induce apoptosis in human hepatoblastoma HepG2 cells (68) and KMS-11 cells through a cytochrome C-mediated activation of caspase-3 and caspase-8 proteases and inhibition of the fibroblast growth factor receptor 3 (FGFR3) expression. Incubation of leukemic cells HL260 with compound K produced apoptosis in the cells in a concentration- and time-dependent manner with morphologic changes in chromatic agglutination, atrophy, and nuclear fragmentation (69). Compound K suppressed melanoma cell proliferation in B16-BL6 mice by activating the protein kinase caspase-3 and releasing cytochrome C in mitochondria into cytoplasm. Western blot test revealed that compound K could elevate p27Kip1 expression, degrade expression of c-Myc and cyclin D1, and induce cell LLC apoptosis through activating caspase-3 protein kinase at the same time. Recently, IH-901 has been reported to induce both G1 arrest and apoptosis, and the apoptosis could be inhibited by COX-2 induction (70).

PHARMACOKINETICS AND METABOLISM

Pharmacokinetics of *P. ginseng* cannot be directly performed using the conventional analytical methods because *P. ginseng* root contains many ingredients, and the amounts of each ingredient vary with different conditions. All these make it more complex and even impossible to directly conduct pharmacokinetics of ginseng itself. The practical way, however, to conduct ginseng's pharmacokinetics is to measure individual ginsenoside's absorption, distribution, metabolism, and elimination in animals and human beings.

Rg₁ and Rb₁ were shown to be metabolized at the gastrointestinal level. In the acidic medium of the stomach, they are immediately decomposed into different ginsenoside metabolites whose chemical structures have been partially determined. Pharmacokinetic studies conducted in rats revealed only 23% absorption of ginsenosides (Rb₁) after a period of 2.5 hours (71). Very small recoveries of these ginsenosides were made in the liver (e.g., 0.25% dose) and heart (<0.1% dose), while the majority of the material was recovered in the small intestine. The bioavailability of bioactive ginseng constituents appears very limited, as evidenced by the low absorption rates for orally administered Rg₁ (0.1% dose) and Rg₂ (1.9% dose), and only little of the original ginsenoside material was recovered in the feces (<1% dose) (72). In our view, the limited amounts of ginsenosides recovered from tissues, urine, and feces are not surprising because the total content of ginsenosides (saponins) in a ginseng is usually less than 5% of its weight, as we mentioned earlier. Moreover, ginsenosides have poor oral bioavailability as demonstrated earlier mainly because of their extensive presystemic metabolism

and poor membrane permeability. A study performed with mini-pigs showed, after intravenous administration, that the derivatives of protopanaxatriol, such as Rg₁, have a one-compartment pharmacokinetic profile, and a half-life of approximately 30 minutes. On the other hand, for those of protopanaxadiol, such as Rb₁, the half-life is much longer (approx. 16 hours), and their pharmacokinetics are described by a two-compartment model (73).

Metabolism pathway of ginsenosides in the gastrointestinal tract of humans could be elucidated following the oral administration of a standardized *P. ginseng* extract. Within the framework of a pilot study, human plasma and urine samples of two subjects were screened for ginsenosides and their possible degradation products. In general, the urine data coincided well with the plasma data, and in both volunteers, the same hydrolysis products, which are not originally present in the extract ingested, were identified. It was shown that two hydrolysis products of the protopanaxatriol ginsenosides, namely G-Rh₁ and G-F₁, may reach the systemic circulation. In addition, compound K, the main intestinal bacterial metabolite of the protopanaxadiol ginsenosides, was detected in plasma and urine. In contrast to previous reports, G-Rb₁ was identified in the plasma and urine of one subject (74).

In conclusion, the ginsenosides are degraded by the acidic medium of the stomach as well as by the intestinal enzymes and intestinal bacteria, therefore the ginsenosides are considered as prodrugs, and G-Rh₁ and G-F₁ are probably the metabolites responsible for the ginsenoside action in humans (74,75).

PRECLINICAL SAFETY EVALUATION

The results of several toxicity studies in animals with a *P. ginseng* extract have been reviewed (76) and demonstrate that a standardized *P. ginseng* extract has a very large therapeutic index. These studies included acute, subacute, chronic toxicity, and teratogenic activity performed in mice, rats, rabbits, pigs, and dogs, and mutagenicity tests (Ames, DNA-repair, mouse-bone micronucleus, chromosomal aberration in human lymphocytes), as well as the safety assessment on the cardiovascular and hormone system.

In a single dose toxicity study, the LD₅₀ after oral administration is >5 g/kg in rats, >2 g/kg in mini-pigs, and >1 g/kg in mice, and after i.p. administration, it is >1 g/kg in rats and mice. No noticeable changes of cardiovascular parameters such as electrocardiogram (ECG), pulse, blood pressure, cardiac output, and stroke volume were observed after single dose oral administration of 0.25, 0.5, and 2.0 g/kg in mini-pigs.

In repeated dose toxicity study, no hematological or histological abnormalities were observed in rats after 20 days of daily oral administration of 4.0 g/kg. Treatment-related hematological or histopathological effects were not noticed in beagle dogs after oral administration of 1.5, 5.0, and 15 mg/kg for 90 days.

In reproduction toxicity study, no decrease of growth rate or reproduction and no treatment-related hematological or histopathological findings were seen in rats for 33 weeks in a two-generation study with daily oral administration of 1.5, 5.0, and 15 mg/kg.

In terms of embryo, fetal, and perinatal toxicity concerns, no abnormalities of fetal development have been detected in rats after daily oral administration of 40 mg ginseng extract/kg on days 1 to 15 after mating, or in rabbits after daily oral administration of 20 mg/kg on days 7 to 15 after mating. In an in vitro study using whole rat embryo culture model, ginsenoside Rb₁ induced teratogenicity (77). The significance of this study is uncertain due to the concentration of Rb₁ used, and to the fact that it is known that ginsenosides that are not metabolized by the acidic medium and intestinal flora exert hemolytic activities (as is generally observed with saponins).

No genotoxicity was observed in the hepatocyte DNA repair test using concentrations of 0.1 to 10 mg/mL of ginseng extract with or without ginsenosides or using 1 to 50 µg/mL of ginsenoside Rg₁. Neither has mutagenicity been observed in *Salmonella typhimurium* and Chinese Hamster V79 cells.

CLINICAL STUDIES

Learning and Memory Effects

In humans, ginseng or ginseng extract showed significant effects on neurological and psychiatric symptoms in aged humans and psychomotor functions in healthy subjects (78). This positive effect of ginseng on cognition performance is due to the direct action of ginseng on the hippocampus. Consistent with the study, Wen et al. (45) demonstrated that red ginseng, ginseng powder, and ginsenoside Rb₁ administration for seven days prior to ischemia rescued the hippocampal CA1 pyramidal neurons and subsequently ameliorated learning deficits in gerbils. The influence of ginsenoside Rg₁ on the proliferating ability of neuronal progenitor cells may serve as an important mechanism underlying its nootropic and antiaging effects particularly on learning and memory (79).

On the other hand, Persson et al. (80) recruited 3500 community-dwelling volunteers to investigate whether the use of ginseng or ginkgo biloba for a long period of time (up to two years) has positive effects on performance on learning and memory. They found that the use of neither ginkgo biloba ($n = 40$) nor ginseng ($n = 86$) was associated with enhanced memory performance in any of the eight memory tests examined, relative to control groups either using or not using nutritional supplements. The study did not provide any quantifiable beneficial effects of ginseng on memory performance. This result coincides with the finding of Sorensen and Sonne (81) who reported that ginseng intake did not enhance memory functions. The investigators admitted, however, that "the study lacked direct control of dosage and specificity of formulas used such as measure of daily or weekly intake and the specific brands that were used."

The effects of 400 mg/day of a ginseng extract on a variety of cognitive functions were compared with placebo in a double-blind randomized study in which 112 healthy volunteers older than 40 years (55 on ginseng, 57 on placebo) were treated for eight to nine weeks. The ginseng group showed a tendency to have faster simple reactions and significantly better abstract thinking than the controls. However, there was no significant difference between the two groups in concentration, memory, or subjective experience (81).

A study investigated whether acute administration of standardized ginseng extract had any consistent effect on mood and four aspects of cognitive performance (quality of memory, speed of memory, quality of attention, and speed of attention) that can be derived by factor analysis of the Cognitive Drug Research computerized assessment battery. The study followed a placebo-controlled, double-blind, balanced crossover design. Twenty healthy young adult volunteers received 200, 400, and 600 mg of the extract, and a matching placebo, in counterbalanced order, with a seven-day washout period between treatments. Following a baseline cognitive assessment, further test sessions took place 1, 2.5, 4, and 6 hours after the day's treatment. The most striking result was a significant improvement in "quality of memory" and the associated "secondary memory" factor at all time points following 400 mg of ginseng. Both the 200 and 600 mg doses were associated with a significant decrement of the "speed of attention" factor at later testing times only. Subjective ratings of alertness were also reduced 6 hours following the two lowest doses (82).

Physiological Performance

In a double-blind crossover study, 12 student nurses working night shifts (three to four consecutive nights followed by three days of rest) were given 1.2 g of ginseng roots or placebo for the first three consecutive nights and tested on the morning after the third night. Crossover medication was given after an interval of at least two weeks. A third series of tests was carried out during normal daytime working, after no medication and following a good night's sleep (GNS). The subjects assessed their mood, physical well-being, and degree of lethargy by means of linear self-rating scales. Two psychophysiological performance tests and hematological tests were also carried out.

The detrimental effects of night shifts were clearly seen. A constant trend in favor of ginseng compared with placebo was noted. Ginseng ratings were favorable for mood criteria, but not for physical well-being symptoms. Ginseng restored blood glucose levels raised by night shift stress. A small but consistent anti-fatigue activity of ginseng was concluded (83).

Various tests of psychomotor performance were carried out in a cohort of 16 healthy male volunteers given a standardized ginseng extract (100 mg ginseng extract twice a day for 12 weeks) and in a similar group given placebo under double-blind conditions. A favorable effect of ginseng relative to baseline performance was observed in attention (cancellation test), processing (mental arithmetic, logical deduction), integrated sensory-motor function (choice reaction time), and auditory reaction time. However, end performance of the ginseng cohort was only statistically superior ($P < 0.05$) to the placebo group in mental arithmetic. No difference between ginseng and placebo was found in tests of pure motor function (tapping test), recognition (digit symbol substitution), and visual reaction time (78).

In a double-blind, placebo-controlled, crossover study, 43 top triathletes received either placebo or 200 mg of a standardized ginseng extract per day for periods of 10 weeks, respectively. Significant differences ($P < 0.05$) in various endurance parameters were only seen after the

second treatment phase. It was concluded that ginseng improves endurance (resistance against end of season stress), but not optimum performance (84).

Twenty top class male athletes received 200 mg standardized ginseng extract per day for nine weeks. In the bicycle ergometer exercise test lasting eight minutes, the post-treatment values were higher for maximal oxygen absorption and lower for blood lactate level and heart rate during exercise compared with pretreatment values. The differences were significant ($P < 0.001$) (85).

A double-blind study involved 30 athletes who received daily either placebo ($n = 10$), 200 mg ginseng extract standardized to 7% ginsenosides ($n = 10$), or 400 mg vitamin E and 200 mg ginseng extract standardized to 4% ginsenosides ($n = 10$) for nine weeks. The same bicycle ergometer test was used and statistically significant variations in heart rate ($P < 0.05$), blood lactate ($P < 0.01$), and maximal oxygen absorption ($P < 0.01$) after exercise between either of the two ginseng preparations and placebo were found. Differences between the two ginseng preparations were not statistically significant. The levels of testosterone and luteinizing hormone in plasma, and free cortisol in urine, were unchanged after all treatment periods (86).

A further double-blind placebo-controlled study with 28 top class male athletes examined the persistence of the effects of nine-week's treatment (placebo or 200 mg ginseng extract with 4% ginsenosides) beyond the treatment period. Ginseng resulted in a significant improvement of maximal oxygen uptake during exercise ($P < 0.01$), heart rate at maximal exercise ($P < 0.001$), forced expiratory volume ($P < 0.01$), forced vital lung capacity ($P < 0.05$), and visual reaction time ($P < 0.01$) compared with placebo. These positive effects lasted for at least three weeks after treatment, and it was concluded that the effects of ginseng are based on clinically relevant metabolic changes that persist for a certain period after treatment (87).

In a double-blind placebo-controlled study with 50 ambulatory patients suffering from asthenia, depressive syndrome, or neurovegetative disorders, the effects of eight weeks' treatment with 200 mg/day of a standardized ginseng extract on performance in two psychometric tests and on results from a comprehensive psychological questionnaire (Sandoz Clinical Assessment Geriatric) were studied. Significant improvement ($P < 0.05$ and $P < 0.01$) was seen in most of the parameters (88).

In a randomized double-blind study, 31 healthy male volunteers received 200 or 400 mg ginseng extract per day for eight weeks. Ginseng had no effect on oxygen consumption, respiratory exchange ratio, minute ventilation, blood lactic acid concentration, heart rate, and perceived exertion (89).

In another randomized double-blind study, 19 healthy female volunteers received daily 200 mg ginseng extract or placebo for eight weeks. It had no effect on maximal work performance and resting, exercise, recovery oxygen uptake, respiratory exchange ratio, minute ventilation, heart rate, and blood lactic acid levels (90).

In a double-blind, placebo-controlled, crossover study in eight healthy volunteers (mean age 25 years) who regularly practiced physical activities, 30 days of daily oral treatment with 400 mg of a standardized ginseng ex-

tract did not improve performance at supramaximal exercise (125% of the maximum aerobic power on bicycle ergometer), nor did it influence blood lactate or blood testosterone (91).

In a study on blood oxygenation status of eight males and two females middle-aged subjects (average 50-year-old), a significant ($P < 0.05$) increase of resting arterial PO_2 was found after four weeks' oral treatment with 200 mg standardized ginseng root extract per day. The resting arterial PO_2 was increased by 4.5 mmHg. In synergy with oxygen treatment, the increase was 10.1 mmHg. Venous PO_2 was decreased (4.3 mmHg) (92).
